Abstract

Diagnostic imaging refers to a variety of new innovative techniques to identify disease or injury via images representing the internal anatomic structure of the human body. This entry

INTRODUCTION

In drug research and development, diagnostic imaging refers to a variety of new innovative techniques to identify disease or injury via images representing the internal anatomic structure of the human body. Physicians use the resulting images to diagnose various medical illness or injury so that patient treatment and therapy can be specifically planned and implemented. The history of diagnostic imaging refers to the radiology, which began as a medical subspecialty in the first decade of the 1900s after the discovery of X-rays by Professor Roentgen. However, the radiology has grown extensively since World War II, where X-ray imaging was used broadly. In the past 25 yr, the digital computer and the new imaging modalities such as ultrasound and magnetic resonance imaging (MRI) have combined to create an explosion of the diagnostic imaging techniques increasingly. In today's health care system, the diagnostic imaging is a key tool in the early diagnosis and prevention of disease.

OVERVIEW

In general, the medical imaging drug products use medical imaging methods to provide information on anatomy, physiology, and pathology. The commonly used methods are radiology, computed tomography (CT), ultrasonography, MRI, and radionuclide imaging. The term *images* can be used as films, likenesses, or other renderings of the body, body parts, organ systems, body functions, or tissues. For example, an image obtained with an MRI contrast agent may refer to a set of images acquired with different pulse sequences and interpulse delay times. An illustration of the medical imaging, as shown in [Fig. 1](#), uses MRI to provide remarkably clear and detailed pictures of the living internal body. Usually, images are created from the computerized acquisition of digital signals.

There are two types of medical imaging drugs: contrast drug products and diagnostic radiopharmaceuticals. The

intentions of a medical imaging drug are twofold: (1) delineate nonanatomic structures such as tumors or abscesses and (2) detect disease or pathology within an anatomic structure. The differences of these two types of medical imaging drugs are described as follows.

Contrast Drug Products

Contrast drug products are used to increase the relative difference of the signal intensities and to provide the additional information in combination with an imaging device beyond the device alone. That is, imaging with the contrast drug product should provide more information than that without the contrast drug product. The most commonly used contrast drug products that are in combination with medical imaging devices are listed in [Table 1](#).

Diagnostic Radiopharmaceuticals

The diagnostic radiopharmaceuticals are radioactive drugs that contain a radioactive nuclide that may be linked to a ligand and a carrier. These products are used in planar imaging, single-photon emission computed tomography, positron emission tomography, or with other radiation detection probes.

Diagnostic trials are clinical trials with diagnostic outcomes needed to establish for therapeutic or diagnostic products under study. Because of the different considerations in designs, the techniques in evaluating the performance of diagnostic medical products are much different from those in evaluating therapeutic pharmaceuticals or from nondiagnostic devices.

REGULATORY REQUIREMENTS

Medical imaging drugs are generally governed by the same regulations as other drug and biological products.^[1]

Fig. 1 Frontal and side view of human body by MRI
(From Imaginis Corporation, sponsored by SIEMENS.)

Table 1 The Combination of Contrast Drug Products with Medical Imaging Devices

Modality	Contrast drug products
X-ray and CT	Iodine agents (photon scattering)
MRI	Gadolinium, dysprosium, and helium
Ultrasound	Liposomes and microbubbles
Suspensions nuclear	Tc-99m, TI-201, indium, and samarium

However, medical imaging drugs have their special characteristics in drug development. In 1998, Food and Drug Administration (FDA) proposed a rule to amend the drug and biologics regulations and add provisions for the evaluation and approval of *in vivo* radiopharmaceuticals used in the diagnosis or monitoring of disease (63 FR 28301, 1998).

The proposed rule was a response to the requirements of the FDA Modernization Act of 1997. The most current guidance for developing medical imaging drugs and biological products in planning and coordinating their clinical investigations and the FDA submission are shown in the draft guidance in June 2000. This draft guidance elaborates on the concepts contained in the proposed rule on radiopharmaceutical diagnostic products entitled *Developing Medical Imaging Drugs and Biological Products*.^[1]

STUDY DESIGN CONSIDERATIONS

Good diagnostic trials have diagnostic endpoints consistent with a well-planned clinical setting. Ideally, the trial is sufficiently controlled to show that the added value of the diagnostic agent and endpoints are objectively defined. That is, good diagnostic trials should be able to translate the effect of a new agent in terms of clinical utility. In efficacy evaluation of imaging studies, it is very often that the study design is based on the results from two individual components. The first one is the clinical component, which is often designed as an open label, nonrandomized, and with noncontrast image as the “control.” In addition to the clinical component, imaging trials may also have the second component that is an off-site “blinded-read” component.

The designs of both components are shown in “Clinical Component” and “Blinded-Read Component.” Potential bias of each component is discussed in “Bias Considerations.” Moreover, the commonly used methods to measure the reader agreement for blinded-read studies are given in “Assessing Reader Agreement for a Blinded-Read Trial.”

Clinical Component

There are many types of designs in clinical component of diagnostic trials. The most commonly used designs are the parallel group design and the crossover design. The choice of clinical designs for a diagnostic trial is often determined by patient population and disease type.

In the parallel group design, the subjects are randomized to one of two or more arms. A different treatment has been allocated to each arm. These treatments include the investigational product at one or more doses and one or more control treatments, such as placebo and/or active comparator. The assumptions underlying this design are less complex than most of other designs. However, similar to other designs, there may be additional features of the study design that complicate the analysis and interpretation (e.g., covariates, repeated measurements over time, interactions between design factors, dropouts, and withdrawals). Parallel group trials generally require large sample sizes to show noticeable effect and may mask important differences in test capabilities. Parallel designs are not practical for hard-to-enroll populations either.

In the crossover design, each subject is randomized to a sequence of two or more treatments, and hence acts as its own control for treatment comparison. This simple maneuver is attractive primarily because it reduces the number of subjects and usually the number of assessments needed to achieve a specific power, sometimes to a marked extent. In the simplest 2×2 crossover design, each subject receives either one of the two treatments in a randomized order in two successive treatment periods, often separated by a washout period. The most common extension of this entails comparing n treatments in n periods, each subject receiving all n treatments. Crossover designs enable better measuring effect of a new test. However, such designs may not be practical either and often involve ethical issues. When the crossover design is used, it is critical to avoid carryover, i.e., the residual influence of treatment in subsequent treatment periods. Furthermore, the crossover design should generally be restricted to situations when loss of subjects from the trial is expected to be small.

Blinded-Read Component

In addition to a clinical component, imaging trials may also have an off-site “read” component. The off-site read has its own design and is often called “blinded-read.” The goal of the blinded-read is to control for investigator bias. A good image viewing strategy guards against bias and avoids introducing effects confounding the clinical component. Therefore the readers who read the images are those who are *independent* and *blinded*. The *independent* are those who have not participated in studies and who are not affiliated with the sponsor or with institutions in which the studies were conducted. The meaning of *blinding* differs from the common way the term is used in therapeutic clinical trials. *Blinded* are those who are unaware of (1) treatment identity used to obtain a given image and (2) patient-specific clinical information or study protocol. However, the specific information provided may depend on the modality under study, the type of agent, and the proposed indication. Three commonly used methods for blinded-read of imaging evaluations are described as follows:

- i. Fully blinded image evaluation—readers have no knowledge of treatment identity, results of the evaluation with the true standard, final diagnosis, or any patient-specific information (e.g., history, laboratory results, and results of other imaging study).
- ii. Imaging evaluation blinded to outcome—readers have no knowledge of the results of the evaluation with the true standard, treatment identity, the final diagnosis, or patient outcome. However, the readers may have knowledge of particular elements of patient-specific information, such as the results of other imaging studies.
- iii. Sequential unblinding—readers evaluate images progressively on each read. The typical evaluation of a

three-step process is: Step 1, perform a fully blinded image evaluation, and record and lock the data. No data can be changed when additional information is available; Step 2, perform an image evaluation which is blinded to outcome, and recorded and locked in the data set; Step 3, compare the result of the above two blinded evaluations to the true standard (or the final diagnosis of the patient outcome). If sequential unblinding is considered, the primary one for determining efficacy should be specified before the study begins.

Bias Considerations

In clinical trial, almost all endpoints in a study may be subject to bias because of different sources. Bias means that the results observed reflect other factors in addition to the effect of the treatment. Similarly, there are many sources of systematic and random errors that are unique to the imaging studies. For example, by using a new ultrasound contrast agent, the bias may come from the poor training and inadequate skill of operators; unclear specifications and settings for device; uninformative response in patient’s characteristics; misinterpretation of the results from the radiologist/clinician; and the information from the gold standard is not the truth. In summary, the commonly encountered bias in study design of diagnostic imaging is listed below for open-label trial and blinded-read trial, respectively.

Bias for an Open-Label Trial

The major disadvantage of the open label is the influence of the response to treatment because of the knowledge of treatment identity. For example, patients who know that they have been assigned to receive the new ultrasound contrast agent may have favorable expectations or increased anxiety, and patients who are not on the new or experimental treatment may become dissatisfied and may drop out of the trial in large numbers. Therefore the open-label trial is particularly prone to bias when the outcome measures are subjective. Other primary biases for an open-label trial in diagnostic imaging studies can be:

- Knowledge of patient clinical information including results from other diagnostic tests (truth standard result and/or comparator result) may affect the way the assessor assesses the outcomes.
- Knowledge of trial protocol and study objectives (entry criteria and effects on pretest probabilities) may affect the way the investigator deals with the patient.
- Image collection (device operation/imaging window) may be influenced in data compilation if the knowledge of treatment identity is not covered.

Bias for a Blinded-Read Trial

It is obvious that the blinded image evaluation can minimize the risk for outcome assessment. Particularly, blinding is useful in reducing bias when determining the performance characteristics for a new treatment compared with the comparator product. However, there are still many situations that biases for blinded-read trial are unavoidable in diagnostic imaging, which are listed below:

- Test drug or imaging modality may be obvious to an examiner. For example, the instructions for image evaluations may differ according to treatment. Therefore blinding to treatment identity may be infeasible.
- The reader can recall image placement and reading order. For example, in an independent evaluation of the unenhanced and enhanced images, the reader may remember the images that were obtained at different times used to a specific tumor. Therefore the effect of randomizing the images during the study is no longer effective for those readers with long-term memory. In a combined image evaluation, the reader often evaluates unenhanced and enhanced images concurrently. The likelihood of bias may increase because of the confounding effects from multiple images (e.g., by systematic overreading or underreading particular findings on images).
- Missing information was concluded for nondiagnostic or uninterpretable images. Therefore the imaging data may be lost if there was no additional information available. However, this would not be more reflective of the clinical setting for the use of contrast agent.

Assessing Reader Agreement for a Blinded-Read Trial

As indicated in the draft guidance,^[1] at least two independent, blinded readers (and preferably three or more) are recommended for each study that is intended to demonstrate efficacy. This allows an evaluation of the reproducibility of the readings (interreader variability). The purpose is to provide a better basis for the subsequent generalization of the findings in the studies. Ideally, each reader should review all the images to give an unbiased evaluation of images. However, this is impractical for large studies.

To facilitate the consistency among readers, the common approach is to assess the reader agreement quantitatively. Suppose that n_{ij} and p_{ij} are the number of patients and the proportion of patients in the i th category by the first reader and j th category by the second reader from a total of k categories, respectively, where $i, j = 1, 2, \dots, k$. The most commonly used statistical method to measure the consistency among readers is the kappa statistic,

which is based on the count data to measure the reader agreement, and was introduced by Cohen.^[2] It is developed as a measurement of nominal scale agreement among readers, particularly applied to the problems of the reliability or reproducibility of the diagnostic tests. The underlying assumption of the kappa statistic, κ , is that the two response variables are independent ratings from N subjects, where

$$N = \sum_{i=1}^k \sum_{j=1}^k n_{ij}$$

$$\text{Kappa Statistics : } \kappa = \frac{p_o - p_e}{1 - p_e}$$

where

$$p_o = \sum_{i=1}^k p_{ii} = \sum_{i=1}^k \frac{n_{ii}}{N}$$

= proportion of observed agreement

$$p_e = \sum_{i=1}^k \sum_{j=1}^k p_{ig} p_{gj}$$

= proportion of expected agreement

The meaning of strength of reader agreement was defined by Landis and Koch^[3] based on the magnitude of kappa statistics. It is shown as below:

Kappa statistic range	Strength of reader agreement
0.81–1.00	Almost perfect
0.61–0.80	Substantial
0.41–0.60	Moderate
0.21–0.40	Fair
0.00–0.20	Slight
<0.00	Poor

The variance of κ is given by

$$\text{Var}(\kappa) = \frac{A + B + C}{N(1 - p_e)^2}$$

where

$$A = \sum_{i=1}^k p_{ii} [1 - (p_{ig} + p_{gj})(1 - \kappa)]^2$$

$$B = (1 - \kappa)^2 \sum_{i,j} p_{ij} (p_{ig} + p_{gj})^2$$

$$C = [\kappa - p_e(1 - \kappa)]^2$$

The kappa value is +1 for complete agreement and zero if the agreement is the same as by chance alone; on the other hand, the value becomes -1 for complete disagreement.

Furthermore, Brenner and Kliebsh^[4] proposed a weighted kappa coefficient on the number of categories as shown below.

$$\kappa_w = \frac{p_{0w} - p_{ew}}{1 - p_{ew}}$$

where

$$p_{0w} = \sum_{i=1}^k w_{ij} p_{ii}$$

and

$$p_{ew} = \sum_{i=1}^k \sum_{j=1}^k w_{ij} p_{ig} p_{gj}$$

The variance of the weighted kappa yields

$$\text{Var}(\kappa_w) = \frac{1}{n(1 - p_e)^2} \left(\sum_{i=1}^k \sum_{j=1}^k p_{ij} [w_{ij} - (w_i + w_j)(1 - \kappa_w)]^2 - [\kappa_w - p_{ew}(1 - \kappa_w)]^2 \right)$$

The common kappa weights for categorical data are:

1. Cicchetti–Alison weight, which is inversely proportional to the distance from the diagonal, such that:

$$w_{ij} = 1 - \frac{|C_i - C_j|}{C_k - C_1}$$

where C_i and C_j are the category of response for readers 1 and 2, respectively, and C_k and C_1 are the maximal and minimum category of response, respectively, and

2. Fleiss–Cohen weight, which is inversely proportional to the squared distance from the diagonal, such that

$$w_{ij} = 1 - \frac{(C_i - C_j)^2}{(C_k - C_1)^2}$$

In general, kappa statistics are suitable for the agreement in qualitative measurements. To measure the interrater agreement in quantitative data, the intraclass correlation is useful. The intraclass correlation coefficients (ICCs) are designs used to assess consistency or conformity between two or more quantitative measurements. They can be used for investigating the properties of reliability, validity, and reproducibility. The commonly used method to estimate the ICC is formulated by the analysis of variance (ANOVA) model. For example, assume that each of the N patients is rated by each of the same two raters and the

data for agreement is normally distributed. Then, it yields a two-way ANOVA model illustrated below:

Source of variation	Degrees of freedom	Mean squares
Between patients	$N - 1$	MSB
Within patients	N	MSW
Between raters	1	MSR
Residual	$N - 1$	MSE
Total	$2N - 1$	

The ICC is given by:

$$\text{ICC} = \frac{\text{MSB} - \text{MSE}}{\text{MSB} + \text{MSE}}$$

For number of rater $k > 2$, the ICC yields

$$\text{ICC} = \frac{\text{MSB} - \text{MSE}}{\text{MSB} + (k - 1)\text{MSE}}$$

Additional information on the intraclass correlation can be found in Snedecor and Cochran.^[5]

DIAGNOSTIC PERFORMANCE MEASURES

To determine how well a diagnostic imaging agent can distinguish between diseased subjects and nondiseased subjects, the outcome may often be classified into one of the four groups depending on (1) whether a disease is present and (2) the results of the diagnostic test of interest (positive or negative). The outcomes are shown in the following 2×2 contingency table:

Test result	Disease		Total
	Present	Absent	
Positive	a	b	$a + b = m_1$
Negative	c	d	$c + d = m_2$
Total	$n_1 = a + c$	$n_2 = b + d$	$N = a + b + c + d$

In the above table, the number in each cell is denoted as the frequency count, which are called the true positive (denoted by a), false positive (denoted by b), false negative (denoted by c), and true negative (denoted by d). The further notations are defined as below:

Total with positive test: $m_1 = a + b$.
 Total with negative test: $m_2 = c + d$.
 Total with disease: $n_1 = a + c$.
 Total without disease: $n_2 = b + d$.
 Total in study: $N = a + b + c + d$.

To demonstrate the efficacy of the agent, the commonly used measurements in diagnostic accuracy are illustrated in the following table.

<i>Diagnostic accuracy</i>	<i>Formula</i>	<i>Interpretation</i>
Accuracy	$(a + d)/N$	The proportion of cases that considers both positive and negative test results for which the test results are correct.
Likelihood ratios	$LR(+)= (a/n_1)/(b/n_2)$ $LR(-)= (c/n_1)/(d/n_2)$	• $LR(+)$ is the probability of a positive test result in subjects with the disease compared with the probability of a positive result in subjects without the disease. • $LR(-)$ is the probability of a negative test result in subjects with the disease compared with the probability of a negative result in subjects without the disease.
Negative predictive value	d/m_2	The probability that a subject does not have the disease given that the test result is negative.
Positive predictive value	d/m_1	The probability that a subject has disease given that the test result is positive.
Odds	$\frac{(a/m_1)/(b/m_1)}{(c/m_2)/(d/m_2)} = \frac{(a/n_1)/(b/n_1)}{(c/n_2)/(d/n_2)} = \frac{ad}{bc}$	The probability that an event occurs compared with the probability that the event will not occur.
Posttest odds of disease	For positive test result, posttest odds of disease = a/b For negative test result, posttest odds of disease = c/d	The posttest odds of disease is the odds of disease in a subject after the diagnostic test results are known. It should be noted that the posttest odds of disease is equal to the pretest odds of disease multiplied by the likelihood ratio.
Posttest probability of disease	For positive test result, posttest probability of disease = a/m_1 For negative test result, posttest probability of disease = c/m_2	The posttest probability of disease is the probability of disease in a subject after the diagnostic test results are known.
Sensitivity	a/n_1	The probability that a test result is positive given that the subject has a disease.
Specificity	d/n_2	The probability that a test result is negative given that the subject does not have a disease.

It is to be noted that the accuracy of the information determined from a diagnostic test requires a judicious choice of a comparator agent or procedure. In other words, the presence of disease is often determined by a truth standard or gold standard. A true standard or gold standard is an independent method of measuring the same variable being measured by the investigational drug that is known or believed to give the truth state of a patient or true value of a measurement. The true standards are used to demonstrate that the results obtained by the medical imaging drug are valid and reliable. The potential gold standard for a diagnostic clinical trial includes:

- Histopathology.
- Therapeutic response.
- Clinical outcome.
- Another diagnostic test.
- *In vitro* tests.
- Animal autoradiography.
- Autopsy.

For example, for a MRI contrast agent intended to visualize the number of lesions in liver or determine whether a mass is malignant, the gold standard might include results from the pathology or long-term clinical outcomes.

The common methods used to test for the differences in diagnosis include the McNemar test, Stuart Maxwell test, and the confidence intervals for sensitivity and specificity. In addition, the receiver operating characteristic analysis is another alternative that can be used to evaluate diagnostic accuracy.^[6]

CONCLUSION

Although kappa statistics are appropriate for testing whether the agreement exceeds the chance levels for binary and nominal ratings, kappa is an omnibus index of agreement. It has no distinctions among various types and sources of agreement. Also, kappas are not comparable across studies, procedures, or populations.^[7,8] The major limitation of the kappa statistic is to require that an observation be an assignment of a subject to only one response category; also, it requires equal number of observations per subject. Kraemer^[9] proposed an extension of the kappa coefficient, which is applied for multiple responses per observation and which allows multiple and not necessarily an equal number of observations per subject.

Another controversial issue for kappa statistics is to use kappa to quantify the levels of agreement. The kappa

was calculated based on the proportion of chance agreement, which is the proportion of times that raters would agree by chance alone. However, this is under the assumption of the independence of raters. The appropriateness of the kappa statistics is questionable when raters are not independent in many applications. In addition, kappa may be low even when there are high levels of agreement between raters. Whether a given kappa value implies a good or bad diagnostic method depends on what model one assumes about the decision making of the raters.^[10]

The sensitivity and specificity are commonly performed for the diagnostic accuracy of the binary data. However, if the correlated samples of the binary data are presented, the true variance of sensitivity and specificity will be underestimated if a conventional standard test is used. The underlying assumption for sensitivity and specificity was for independent observations. To prevent this from happening, the within-subject correlation should be taken into account to estimate the sensitivity and specificity. The examples for dependent observations are: (1) the detected multiple lesions within the same patient and (2) the diagnostic tests to a tooth surface within a patient's mouth. Moreover, these correlated samples of binary data appear in many fields of applications.

Several alternative approaches were proposed for dependent observations in the literature. Sternberg and Hadgu^[11] used a generalized estimating equation (GEE) to estimate the sensitivity and specificity for corrected observations. Lee and Dubin^[12] and Lee^[13] proposed the weighted estimators to calculate the accuracy, sensitivity, specificity, and positive predictive probability for correlated observations. In addition, Ahn^[14] introduced several statistical methods for correlated diagnostic tests based on the assumption that any two observations in the same patient have the same correlation value. Furthermore, the performance of ratio estimator,^[15,16] the intracluster correlation estimator,^[17] the weighted estimator, and GEE estimator were compared in terms of their biases, observed variances, MSE, and relative efficiencies of their variances; also, 95% coverage proportions were compared by Ahn^[14] based on the simulation study.

Diagnostic Procedure: Sensitivity and Specificity

Jiayin Zheng and Shein-Chung Chow

Department of Biostatistics and Bioinformatics, Duke University School of Medicine,
Durham, North Carolina, U.S.A.

Abstract

In biopharmaceutical studies, diagnostic tests are routinely used to screen for, diagnose, grade, and monitor the progression of diseases. To validate and evaluate the performance of a test, it is often compared with a reference standard that reflects the “truth,” and then different measures of accuracy are calculated to see how good is the test at diagnosis of the disease. In this article, we provide a brief introduction of two well-known and widely used measures, sensitivity and specificity.

Keywords: Accuracy; Likelihood ratio; Reference standard; True positive; True negative.

INTRODUCTION

The use of diagnostic tests is common in a physician’s daily practice, aiming to confirm or reject the presence of a disease or health event. Diagnostic information is obtained from a variety of sources, including imaging and biochemical techniques, pathological and psychological assessments, observing signs and symptoms, medical history, and clinical examinations.^[1,2] Ideally, such tests are expected to correctly identify subjects with and without the disease with 100% accuracy. A perfect test will show a negative result for all disease-free subjects and a positive result for all diseased subjects. However, tests are prone to errors. To evaluate a test, multiple aspects are taken into consideration, including reproducibility and accuracy.^[3–5] Reproducibility refers to the ability of producing the same result if the same test is done again.^[6] Accuracy refers to the degree of agreement between the results from the diagnostic test under study and the “truth” (or those from a reference standard).^[7] In this article, we focus on the accuracy and introduce two important measures: sensitivity and specificity.

The definitions of sensitivity and specificity consist of the following four fundamental terms. The terms positive and negative refer to the presence and absence of the condition of interest, respectively.

1. True positive: the test is positive for the diseased patient.
2. False positive: the test is positive for the disease-free patient.
3. True negative: the test is negative for the disease-free patient.
4. False negative: the test is negative for the diseased patient.

Table 1 shows the results of a diagnostic test, with rows summarizing the test results and columns summarizing the “truth.” The number of diseased subjects being positive and negative are denoted by a and c . The number of disease-free subjects being positive and negative are denoted by b and d .

SENSITIVITY AND SPECIFICITY

The sensitivity quantifies the ability of the test to correctly identify the diseased subjects and is defined as the proportion of true positives among the diseased subjects.

$$\text{Sensitivity} = \frac{\text{True positives}}{\text{True positives} + \text{False negatives}} = \frac{a}{a + c}$$

The specificity quantifies the ability of the test to correctly identify the disease-free subjects and is defined as the proportion of true negatives among the disease-free subjects.

$$\text{Specificity} = \frac{\text{True negatives}}{\text{True negatives} + \text{False positives}} = \frac{d}{b + d}$$

The confidence intervals of sensitivity and specificity can be calculated using standard methods for proportions.^[8]

A test with 80% sensitivity correctly detects 80% of diseased subjects, with the remaining 20% undetected. Likewise, a test with 80% specificity correctly reports 80% of disease-free subjects as negative, with the remaining 20% incorrectly identified as positive. In general, the higher the sensitivity, the lower the specificity, and vice versa.

When a test aims at identifying a serious but treatable disease, a high sensitivity is desirable.^[9] However, a high

Table 1 Results of a diagnostic test

Results of the diagnostic test	The “truth” or results of the reference test	
	Disease present	Disease absent
Positive	True positive (a)	False positive (b)
Negative	False negative (c)	True negative (d)

sensitivity alone does not make a good test, as the test also needs to be negative for all disease-free subjects. In other words, high sensitivity is required for a test to be useful at ruling out a disease, and high specificity is required for it to be useful at confirming a disease.^[1] In general, whether one prefers a higher sensitivity but a lower specificity or vice versa is not straightforward. A diagnostic test with a lower sensitivity and specificity could be preferred when the test with better accuracy has a high risk of complications such as some invasive methods with potential complications. In this situation, one may attempt to balance the desirable and undesirable consequences of performing different diagnostic tests.^[10]

Unlike some other measures of accuracy, the prevalence of the disease does not affect the sensitivity and specificity of a diagnostic test.^[11] It is because they are calculated from subgroups of subjects with and without the disease, respectively.

Two other terms, positive likelihood ratio and negative likelihood ratio defined as follows, describe the discriminatory properties of positive and negative results, respectively.

$$\text{Positives likelihood ratio} = \frac{\text{Sensitivity}}{1 - \text{Specificity}} = \frac{a/(a + c)}{b/(b + d)}$$

$$\text{Negative likelihood ratio} = \frac{1 - \text{Sensitivity}}{\text{Specificity}} = \frac{c/(a + c)}{d/(b + d)}$$

They indicate the number of times more likely particular test results are in diseased subjects than in disease-free subjects.^[1] Positive likelihood ratios above 10 and negative likelihood ratios below 0.1 have been noted as providing convincing diagnostic evidence, whereas those above 5 and below 0.2 have given strong diagnostic evidence.^[12] A likelihood ratio close to 1 indicates that the test provides little additional information regarding the presence or absence of the disease.

SOME REMARKS ON PRACTICE

Although the sensitivity and specificity of diagnostic tests are not affected by the disease prevalence and thus can be compared across study populations with different prevalence rates, they can be influenced by differences in disease characteristics (such as disease severity) and characteristics of subjects such as age and gender.^[4] Many

diagnostic tests have been introduced with great enthusiasm because of their high sensitivity and specificity, but have nevertheless been rejected at a later stage. One of the reasons for this rejection was that measures of accuracy of a diagnostic test have often been presented as inherent and fixed properties, whereas in reality, they can be affected by different sources of variation and bias.^[13,14]

Thus, it is critical to evaluate the group of subjects to whom the diagnostic test has been applied when the sensitivity and specificity of two diagnostics tests are compared. Systematic reviews of evaluations of tests are required to produce the estimates of test performance and impact based on all available evidence, to evaluate the quality of published studies, and to account for variation and bias in findings between studies.^[15,16] The important aspects of study quality include the selection of a clinically relevant cohort, the consistent use of a single good reference standard, and the blinding of results of experimental and reference tests.^[1,12] Unless the study is of high quality, its results cannot be included and compared with those from other studies. If the results of studies are reasonably homogeneous, then sensitivities, specificities, and likelihood ratios can be combined directly. Otherwise, appropriate statistical methods for pooling the results should be used to properly address multiple heterogeneity sources between studies and notably variation in diagnostic thresholds.

In recent years, several guidelines have been published on how to report on diagnostic tests, which are recommended for further reading.^[7,10,17]

Disease Modification Effects: Design and Analysis

Djokouri A. Kouassi and Annpey Pong

Merck Research Laboratories, Summit, New Jersey, U.S.A.

Abstract

This entry provides an overview of candidate study designs by reviewing examples of study designs that could prove useful in assessing disease-modifying effects of new drug compounds as well as discussing methods of data analysis.

INTRODUCTION

In drug development, when the cause or etiology of a disease is known, a suitable treatment can be developed to alter its underlying pathogenic process and thereby abate its symptoms. However, for some chronic illnesses such as rheumatoid arthritis, depression, Parkinson's, and Alzheimer's diseases, the etiology is not known and there are as of yet no valid markers for disease progression. Consequently, no therapies that will specifically target the root causes of these maladies have been instituted thus far. In fact, the existing treatments for these disorders have been approved solely on the basis of their symptomatic effects. In other words, these medicines have been proven to relieve the symptoms rather than to disrupt the pathophysiological processes of these diseases. Of course symptomatic treatments or medicines that address only the symptoms are quite useful in providing patients with some degree of comfort. But they also mask the degenerative process of the illness which goes on unchecked for years and ultimately leads to death.

In recent years, the aim of many drug developers has been to provide these growing patient populations with drug products capable of affecting the pathogenic process of these disorders. If developed, such disease-modifying therapies can reasonably be expected to change the natural course of these illnesses, curb their progression, or outright cure them. Unfortunately, the development of such drugs has been thwarted by the lack of knowledge for the etiology of these diseases coupled with the absence of reliable markers for disease progression. Metaphorically, the challenge facing drug makers is nothing less than the daunting task of finding a needle in a haystack. How can a disease modification claim be made in the treatment of an illness about which very little to nothing is known? This is precisely the question that the scientific and regulatory communities have been scrambling to find an answer for. Some scientists have been exploring plausible hypotheses for the etiologic factors involved in the genesis of these diseases.

Others are searching for biological markers that could serve as valuable hints for the progression of the structural decay caused by the diseases, and yet other researchers are investigating clinical trial design strategies that could have the potential to demonstrate disease modification effects. In this chapter, we provide an overview of candidate study designs. Note that none of the design techniques that are discussed here have been used in clinical trials that have led to a successful demonstration of disease modification effects. The section "Design Considerations" will present three study designs that could be useful in assessing disease-modifying effects, if any, of new drug compounds. The section "Methods for Data Analysis" will be devoted to the discussion of likely methods of data analysis, and our concluding remarks will be presented in the "Conclusion."

DESIGN CONSIDERATIONS

Randomized Start/Withdrawal Designs

Randomized start/withdrawal designs were proposed in 1996 and 1997 by Paul Leber,^[1,2] a medical reviewer from the U.S. Food and Drug Administration (FDA), for demonstrating disease-modifying effects of new therapeutic compounds in the treatment of Alzheimer's disease. They are crossover type studies conducted over two periods. In the first period, patients are randomly assigned to either an experimental drug or placebo and treated in a double-blinded fashion. After the first period, all patients receive either the experimental drug (randomized start designs) or placebo (randomized withdrawal designs). The treatment effects are typically assessed at the end of each period. The key rationale behind these designs is that if the drug compound being tested has disease-modifying effects, any treatment difference observed at the end of the first treatment period will be sustained throughout the second. However, if it has only symptomatic effects, then the observed difference will fade away (see [Figs. 1 and 2](#)).

Fig. 1 Randomized withdrawal

Fig. 2 Randomized start

This reasoning is predicated on the assumption that patients randomized to placebo will suffer more structural degradation than their counterparts in the active treatment group during the first period. As a result, they are expected to lag behind during the second treatment period. But, if the test drug has only symptomatic effects, the extent of deterioration in the disease condition of patients in both treatment groups would be similar in the first period. Therefore, any difference observed between the two treatment groups at the end of the first period is expected to vanish when all the patients are administered the same treatment during the second period.

Let $\mathcal{T}_1$ be the actual treatment difference at the end of the first treatment period. This difference could be expressed as the sum of the disease-modifying effect $\mathcal{T}_d$ and symptomatic effect $\mathcal{T}_s$, that is,

$$\mathcal{T}_1 = \mathcal{T}_s + \mathcal{T}_d \quad (1)$$

If $\bar{x}_{1a}$ and $\bar{x}_{1p}$ are the estimated means response at the end of the first period for patients treated with the test drug

and placebo, respectively, a natural estimator of $\mathcal{T}_1$ is the observed treatment difference

$$\hat{\mathcal{T}}_1 = \bar{x}_{1a} - \bar{x}_{1p} \quad (2)$$

Assuming that the outcome measure is normally distributed, a $100(1 - \alpha)\%$ two-sided confidence interval for $\mathcal{T}_1$ is

$$\left[\hat{\mathcal{T}}_1 - SE_1 * t_{\left(\frac{\alpha}{2}; \nu\right)}; \hat{\mathcal{T}}_1 + SE_1 * t_{\left(\frac{\alpha}{2}; \nu\right)} \right], \quad (3)$$

where SE_1 is the standard error of $\hat{\mathcal{T}}_1$ and $t_{\left(\frac{\alpha}{2}; \nu\right)}$ the upper $\frac{\alpha}{2}$ point of the central Student's t distribution with ν degrees of freedom. Clearly, if $\mathcal{T}_1$ is not statistically significant, neither will its components. Since the main purpose of randomized start/withdrawal designs is the estimation of the disease-modifying effect $\mathcal{T}_d$, the treatment difference observed at the end of the first period $\mathcal{T}_1$ must be statistically meaningful to warrant further investigation of the disease-modifying effect.

McDermott et al.^[3] have indicated that $\mathcal{T}_d$, the disease-modifying component of the treatment effect is estimated by

$$\hat{\mathcal{T}}_d = \bar{x}_{2a} - \bar{x}_{2p}, \quad (4)$$

where $\bar{x}_{2a}$ and $\bar{x}_{2p}$ are the estimated mean response at the end of the second treatment period for patients previously treated with the active drug and placebo, respectively. The reliability of this estimate depends upon which one of the two designs (i.e. randomized start and randomized withdrawal designs) is used. For instance, in a randomized withdrawal trial, the symptomatic component of the treatment effect is expected to disappear during the course of the second period when all patients are treated with placebo. Hence, it is conceivable to attribute any treatment difference lingering at the end of the second period to the disease modification activity of the active drug. In other words, in this case, $\mathcal{T}_d$ can reliably be estimated by $\hat{\mathcal{T}}_d$. In a randomized start trial, however, the reliability of $\hat{\mathcal{T}}_d$ hinges on the validity of the assumption that the total incremental change induced by treatment during the second period is the same in both treatment groups. If this assumption does not hold, $\hat{\mathcal{T}}_d$ could lead to erroneous and misleading inferences.

There is no doubt that patients treated the longest with a disease-modifying drug will exhibit, at the end of the trial, the greatest gain in terms of altering the degenerative process of the disease. However, due to the lack of sensitivity of some measuring instruments used to assess change in patients' outcomes, such a benefit may not necessarily translate into a treatment difference sufficiently large to

support a disease modification claim. In other words, $\hat{T}_d$ may be so small that one cannot infer from it a statistically meaningful disease-modifying effect.

To illustrate this point, consider an hypothetical clinical study designed as a randomized start trial for assessing whether a new drug compound has disease-modifying effects in the treatment of patients with mild to moderate Alzheimer's disease (Mini-Mental State Examination (MMSE) scores between 16 and 26 inclusive, with higher scores indicating less severe disease condition). Using a stratified randomization method with MMSE score (<20 ; ≥ 20) as the stratification factor, patients were randomly assigned to either the active drug or placebo. For simplicity, the primary outcome measure was the Alzheimer's Disease Assessment Scale-cognitive subscale (ADAS-cog), a 70-point scale instrument that evaluates cognitive change in patients (higher scores of ADAS-cog are indicative of greater cognitive impairment). The durations of both treatment periods were "adequate" for the disease-modifying effect to appear in the first period and the symptomatic effect to disappear in the second. Both treatment groups were comparable at baseline with respect to ADAS-cog and MMSE scores (see Table 1).

Now, suppose that at the end of the first period, patients in the active drug group showed some improvement in their cognitive ability while those in the placebo group worsened. The means change from baseline in ADAS-cog were 7.5 and 9.3 for the active drug and placebo groups, respectively. From the results in Table 2, the means MMSE scores were 23.8 for the active drug group versus 17.4 for the placebo group.

During the second treatment period however, less change was noted in the ADAS-cog scores for patients initially randomized to the active drug group as opposed to those previously treated with placebo (see table below). At the end of the second period, the treatment difference was so small that for all intended purposes, the two treatment groups were not statistically significantly different from one another as shown in Table 3.

Table 1 Mean Baseline Characteristics of Patients

Endpoints	Treatment groups	
	Active Drug	Placebo
ADAS-cog	23.3	22.9
Disease Severity MMSE	20.6	20.8

Table 2 Mean Cognitive and Disease Severity Results at the End of the First Period

Endpoints	Treatment groups		<i>p</i> -value
	Active Drug	Placebo	
Change from Baseline in ADAS-cog	7.5	9.3	0.034
Disease Severity MMSE	23.8	17.4	

Table 3 Mean Cognitive and Disease Severity Results at the End of the Second Period

Endpoints	Treatment groups		<i>p</i> -value
	Active Drug	Placebo	
Change from Baseline in ADAS-cog	7.1	8.6	0.417
Disease Severity MMSE	24.1	23.9	

Clearly, the trial data failed to provide sufficient evidence to support the claim of disease modification activity. But for the sake of argument, one could think that the small incremental cognitive changes observed during the second period in patients originally randomized to the active drug was due to a lack of sensitivity of the ADAS-cog. Harrison et al.^[4] reported that ADAS-cog is not sensitive for measuring cognitive changes in patients with MMSE scores greater than 18. Because the average MMSE score for patients randomized to the active group was 23.8 versus 17.4 in the placebo group at the end of the first period, it is questionable whether the treatment difference observed at the end of the second period is a true reflection of the disease-modifying effect of the active drug. Hence, in a randomized start design, failure to show a statistically significant treatment difference at the end of the second period is not necessarily indicative of lack of disease modification activity.

As pointed out by Mani,^[5] randomized start/withdrawal designs do have the potential to discriminate between symptomatic and disease-modifying effects of new drug compounds. However, they present a number of serious challenges:

- It is unclear how long the first period must be for the disease-modifying effects to take hold, and how long the second period must be for the symptomatic effects to vanish completely (randomized withdrawal) or to fully appear (randomized start).
- The second treatment period in both designs is not blinded and could be prone to assessment bias.
- It is unclear what effect size for disease modification should be postulated for sample size computation.
- In randomized withdrawal designs, replacing the active drug with placebo could present an ethical issue, especially when the patients are responding to the therapy. This practice has the potential of compromising patient accrual.
- Patients may drop out as their condition worsens. As a result, the missing data mechanism may be not missing at random (NMAR) which complicates further the analysis of the data.

Because of these issues, the implementation of these design techniques by clinical trialists has been very slow and as a result, alternative designs are being sought.

Parallel Group Designs

In a parallel group design, patients are randomly assigned to receive either the active drug or placebo and remain on that treatment for the entire duration of the trial. Most clinical scientists are familiar with parallel group designs; therefore, they are less vulnerable to procedural errors and are more likely to provide better precision for parameter estimation than the new and untested randomized start/withdrawal designs. Parallel group designs are blinded throughout the duration of the treatment. Thus, they are less prone to assessment bias. Assuming that the duration of the trial is long enough for the disease-modifying effects to take hold and the symptomatic effects to vanish, any observed treatment difference at the end of the study can conceivably be attributed to the disease-modification ability of the active drug. But how long a treatment duration is long enough? This question has been and continue to be unanswerable, at least for the time being. Furthermore, it is unclear what effect size for disease modification should be postulated for sample size computation.

METHODS FOR DATA ANALYSIS

Survival Analysis

Survival analysis with death as the endpoint of interest could prove an adequate method for demonstrating disease-modification effect as the treatment associated with the longest median survival time can be assumed to have slowed the progression of the illness. The drawback of this method is that the chronic diseases being discussed progress slowly in time. Thus, clinical trials with death as the primary endpoint will require an excessively long duration in order to observe an adequate number of events. Therefore, in the absence of variables that could be used as valid surrogates for death, survival analysis, though attractive from a theoretical standpoint, is not a practical analysis tool for assessing disease-modifying effects.

Slope Analysis

Slope analysis is a method for comparing the rate of decline of patients in the active group against that of patients in the placebo arm. Although the goal of slope analysis is to demonstrate disease-modifying effect, the interpretation of the difference between the rates of decline in the two treatment groups could significantly vary from one study design to another. In randomized start/withdrawal trials, “similar” rates of decline in both treatment groups during the second treatment period is viewed as a proof of disease-modifying effect. Hence, proving disease modification activity in randomized start/withdrawal trials is tantamount to demonstrating that the difference in the slopes of decline in the two treatment groups is small enough to be considered

scientifically and clinically irrelevant. In other words, randomized start/withdrawal trials will have to be designed as non-inferiority trials which will require large sample sizes. In parallel group trials however, divergent rates of decline with patients randomized to the active group expected to declines lower than their counter parts in the placebo group, are indicative of disease-modifying effect. As a result, parallel group trials will be designed as superiority trials. The duration of a parallel group study has to be long enough so that during the course of the trial disease-modifying effects could take hold while symptomatic effects wear off.

Slope analysis is often conducted in a number of ways. One way is to estimate the slope of decline of each individual patient and use these slope as the dependent variable in appropriate statistical models (see Ref. [6]). Another way is to use the primary endpoint in linear models such as a mixed model for repeated measurements (MMRM), and use the time by treatment interaction to test the equality of the slope of decline in both treatment groups. The main problem is that comparing the slopes of decline between the treatment groups may lead to erroneous conclusions because individual patients often tend to decline at different rates independent of the therapy they are assigned to. Furthermore, patients may drop out as their condition worsens. As a result, the missing data mechanism may be not missing at random (NMAR) which complicates further the analysis of the data.

CONCLUSION

In the treatment of a disease, the observed effect of a medicine could be an expression of its impact on either the root cause of the illness or the symptoms associated with it. If the medicine affects only the symptoms of the disease without any meaningful impact on its root cause, its effects are temporary and last as long as it is administered. However, if the drug alters the root cause of the disease, it will not only relieve the symptoms but its effects will be permanent. Hence, the goal of drug developers is to develop drugs capable of impacting the mechanism responsible for the destructive effects of the illness under study. This goal is attainable when the etiology of the disease is known and the effects of the drug on the key etiologic factors can easily be measured. When the etiology and reliable markers of the disease are unknown however, measuring the impact of the drug on the root cause of the disease is a formidable task, a task in which researchers have to find innovative ways to demonstrate the impact of the drug on the pathophysiological process of the disease. It is in this context that the concept of “disease modification” discussed in this chapter was born. The concept is still evolving, as is the regulatory guidance pertaining to methods for demonstrating disease modification.

Indeed, there is no consensus among the health authorities. As pointed out by Vellas et al.,^[7,8] in order to approve

a disease-modifying therapy, the FDA requires a new drug product to show meaningful effects on the mechanism of action of the target disease. For the European Medicines Agency (EMA) on the other hand, the approval is based on the demonstration of sound clinical outcomes. Hence, the FDA tends to favor randomized start/withdrawal clinical trials for demonstrating disease-modifying effects, whereas the EMA favors the traditional parallel group trials. The statistical methods presented here are consistent with the current understanding of the notion of disease modification. As this concept continues to evolve and more information becomes available on the diseases, the design techniques as well as the analysis methodologies described here will be adapted accordingly.

Dissolution Profile Comparison: Statistical Methods

Harry Yang

MedImmune, LLC, Gaithersburg, Maryland, U.S.A.

Abstract

In vitro dissolution testing is a critical analytical methodology used for monitoring product quality and assessing performance characteristics after scale up and post-approval changes. In this article we review published statistical work on dissolution profile comparison and related regulatory requirements. A Bayesian approach that overcomes many of the statistical issues of the current methods such as f_2 statistic is described in detail.

Keywords: Bayesian model; Dissolution profile; f_2 statistic; *In vitro* release; Multivariate statistical distance; Similarity.

INTRODUCTION

The effectiveness of a drug in a solid oral dosage form, such as a tablet or capsule, relies on the release of the drug substance from the drug product, the dissolution of the drug under physiological conditions, and diffusion of the drug through the gut wall into the body. *In vitro* dissolution testing is used to mimic this *in vivo* process, even acting as a surrogate measure of *in vivo* performance if a strong *in vitro* and *in vivo* correlation is established. Since dissolution testing can be carried out using specialized laboratory equipment, it is relatively fast and inexpensive when compared to *in vivo* studies.

In vitro dissolution testing is used to achieve different objectives throughout the lifecycle of a drug. In the early stages of drug development, it is used to guide formulation development. In process development, it is used to assess the effects of critical manufacturing variables on drug performance. For commercial manufacturing, it can also be used for quality control of scale-up and commercial batches. Furthermore, it is a useful technique for assessing the impact of certain post-approval changes, as described in several regulatory guidelines published since 1997. These numerous regulatory documents cover topics including general recommendations for dissolution testing, approaches for setting dissolution specifications, statistical methods for comparing dissolution profiles, and conditions under which a waiver for an *in vivo* bioequivalence study is granted.

It is of great scientific and regulatory interest to assess the similarity between dissolution profiles. For example, the demonstration of similarity of dissolution profiles before and after a manufacturing or formulation change is a regulatory requirement. Various methods for comparing dissolution profiles have been suggested in both scientific literature and regulatory documents. They fall into two broad categories, namely, model-independent and

model-dependent methods. Among the model-independent approaches, of note are f_2 statistic and multivariate statistical distance (MSD) test. Various model-dependent methods are also used for dissolution profile comparison, including ones dependent on mechanistic models of drug dissolution processes and others on empirical models such as Weibull. More recently, a Bayesian test procedure was suggested that overcomes many of the statistical issues of the current methods.

In this article we review published statistical work on dissolution profile comparison and related regulatory requirements. A detailed critique of the current methods is provided, followed by a Bayesian approach that overcomes many of the issues of the current methods. We also note directions for future research on dissolution profile comparisons.

DISSOLUTION PROFILE COMPARISON

Dissolution Profile

Consider a dissolution study with times $t_i, i = 1, \dots, k$. Let $R_j = (R_{j1}, \dots, R_{jk})'$, $j = 1, \dots, n_1$, and $T_l = (T_{l1}, \dots, T_{lk})'$, $l = 1, \dots, n_2$, be the dissolution measurements of reference tablet j and test tablet l , respectively. For simplicity, we assume $n_1 = n_2 = n$. Of interest is to compare the dissolution profiles of the reference and test products characterized by R_j and T_l . When designing a dissolution experiment, consideration needs to be given to dissolution media, apparatus type, and hydrodynamics such as agitation rate appropriate for the product. A dissolution testing run typically involves dissolving 6–12 dosage units in agitated media, measuring API content by HPLC or UV spectroscopy at set time points. Figure 1 shows a typical dissolution profile which is the curve of measured percent of API dissolved plotted against time.

Fig. 1 Dissolution profiles of test and reference drugs (adapted from Novick et al.^[30])

Statistical Methods for Assessing Similarity

As previously discussed, dissolution profile comparisons can be carried out using either model-independent or model-dependent methods. Here the term “model” refers to the function used to describe the dissolution profile, not the sampling distribution of the response values.

Model-Dependent Approaches

Univariate Methods

Moore and Flanner^[1] proposed a model-independent approach to measure the similarity between drug dissolution profiles of a test and reference formulation. The method includes the calculation of two mathematical indices:

$$f_1 = \frac{\sum_{i=1}^k |\bar{R}_i - \bar{T}_i|}{\sum_{i=1}^k \bar{R}_i} \times 100$$

$$f_2 = 50 \log_{10} \left\{ 100 \left(1 + \frac{1}{k} \sum_{i=1}^k w_i w_i (\bar{R}_i - \bar{T}_i)^2 \right)^{-1/2} \right\}$$

where $\bar{R}_i = \frac{1}{n} \sum_{j=1}^n R_{ij}$ and $\bar{T}_i = \frac{1}{n} \sum_{j=1}^n T_{ij}$ are the sample means of the reference and test results at time t_i , $i = 1, \dots, k$, respectively, and w_i is an optional weighting factor.

The factor f_1 , generally referred to as the difference factor, measures the relative difference in percent (%) dissolution between the two curves by time point. It is equal to zero when the test and reference profiles are identical and becomes larger when the difference between the two profiles increases. The similarity factor f_2 is a measurement of the similarity in the percent (%) dissolution between the two curves. It assumes a value between 0 and 100, with $f_2 = 100$ when the two dissolution curves are identical and decreasing to zero as the dissimilarity between the two profile increases. A similarity test procedure based on similarity factor f_2 with $w_i = 1$ either in combination with the difference factor f_1 or alone, has been recommended in various regulatory publications.^[2–8] In general, it is required that $f_2 \geq 50$ in order to deem two dissolution profiles similar. Thus, while not explicitly stated, inference based on f_2 is seemingly intended to test the hypotheses:

$$H_0 : F_2 \leq 50 \quad \text{versus} \quad H_a : F_2 > 50,$$

where

$$F_2 = 50 \log_{10} \left\{ 100 \left(1 + \frac{1}{k} \sum_{i=1}^k (E[R_i] - E[T_i])^2 \right)^{-1/2} \right\}$$

and, $E(R_i)$ and $E(T_i)$ are the expected values, across the population of dosage units, of the dissolution measurements at time t_i ($i = 1, \dots, k$), from the reference and test batches, respectively.

As noted by Shah et al.^[9] and empirically evaluated by Ma, et al.,^[10] f_2 is a biased estimator of the true similarity measure F_2 . A method of calculating f_2 using a bias correction was suggested by Shah et al.^[9] and Ma, et al. (2000) explored the use of a bootstrap approach to construct a confidence interval on F_2 since the sampling distribution of f_2 is difficult to derive analytically.

A few other model-independent similarity factors have also been suggested in the literature. One based on the index of Rescigno^[11] was originally used to compare plasma drug concentration curves and mean dissolution profiles. As with f_2 , these methods do not explicitly define the statistical hypotheses to be tested for similarity, nor can the operating characteristics of the tests (such as Type I and II errors) be determined at all.

Multivariate Statistical Distance

Another class of model-independent methods hinges on the normality assumption underlying the *in vitro* release values observed at an individual time point and constructs a measure of the distance between two sets of multivariate random variables.^[12] It is assumed that

$$R_{ij} \sim N(\mu_R, \Delta) \quad \text{and} \quad T_{ij} \sim N(\mu_T, \Delta).$$

Let $\bar{R} = (\bar{R}_1, \dots, \bar{R}_k)$, $\bar{T} = (\bar{T}_1, \dots, \bar{T}_k)$ be the sample mean vectors comprised of sample mean values at times t_i , $i = 1, \dots, k$, S_R and S_T the sample variance-covariance matrices for the reference and test lots, respectively, and S_p the pooled sample variance-covariance matrix.

$$S_p = \frac{(k-1)S_R + (k-1)S_T}{2k-2} = \frac{1}{2}(S_R + S_T).$$

Thus $T^2 = n_1 n_2 (n_1 + n_2)^{-1} [(\bar{R} - \bar{T}) - (\mu_R - \mu_T)]' S_p^{-1} [(\bar{R} - \bar{T}) - (\mu_R - \mu_T)]$ is the Hotelling's T^2 statistic. Recall that

$$\frac{n_1 + n_2 - k - 1}{(n_1 + n_2 - 2)k} T^2 \sim F_{k, n_1 + n_2 - k - 1}.$$

Then, a 95% confidence region for $\mu_R - \mu_T$ is obtained as follows:

$$C(\bar{R}, \bar{T}, S_p) = \left\{ T^2 \leq \frac{(n_1 + n_2 - 2)k}{n_1 + n_2 - k - 1} F_{k, n_1 + n_2 - k - 1; 0.05} \right\}.$$

Tsong et al.^[12] proposed a method that compares the maximum Mahalanobis distance

$$D_{M,\alpha} = \sup_{\{(\mu_R, \mu_T) \in C(\bar{R}, \bar{T}, S_p)\}} \sqrt{(\mu_R - \mu_T)' S_p^{-1} (\mu_R - \mu_T)}$$

with the tolerance limit

$$TL = \sqrt{\delta^2 J' S_p^{-1} J},$$

where δ is the maximum allowable dissimilarity (i.e. difference) at any sampling time, and J denotes the $k \times 1$ vector of unities. Similarity is claimed if $D_{M,\alpha} \leq TL$.

However, although $|(\mu_R - \mu_T)_i| \leq \delta$, for $i = 1, \dots, k$, implies $D_{M,\alpha} \leq TL$, the converse is not true. Therefore it is conceivable that the two dissolution curves may have a meaningful difference at one or more individual sampling times, and still have the maximum Mahalanobis distance remain acceptable. Notice also that TL , as defined above, depends on the observed pooled sample variance S_p , calculated from the same data used for the similarity assessment. Thus, the definition of similarity – and the inference about similarity for the two products being compared – will vary from data set to data set.

One issue associated with the above multivariate distance methods, as with the univariate f_1 and f_2 approaches, is the difficulty in assessing their operating characteristics. Saranadasa and Krishnamoorthy,^[13] in an effort to address this shortcoming, developed a multivariate test of size α for assessing the similarity of two dissolution profiles assuming parallelism. Chow and Ki^[14] used a time series approach to account for the correlation between

consecutive time points and overcome the drawback of the multivariate distance methods.

Model-Dependent Methods

Model-dependent methods are also listed in regulatory guidance documents as alternative procedures for dissolution profile similarity testing for both IR and MR products. These rely on describing dissolution profiles through mathematical functions, based on understanding of the dissolution processes underlying the dissolution measurements over time. Because biological systems and related physio-chemical processes involved in drug dissolution are exceedingly complex, both mechanistic models^[15–19] and empirical models have been proposed to describe dissolution concentration-time profiles. Empirical functions that can be used to fit the dissolution profiles include Weibull,^[20] exponential, probit, Gompertz, and logistic.^[21] In general, the Weibull is considered to be the most flexible able to describe a wide variety of profile shapes.^[22] More recently, linear mixed effects and non-linear mixed effects models have been suggested.^[23,24] One advantage of these methods is that they permit an explicit specification of the covariance structure of the data. Potential pitfalls of these methods are: 1) the model parameters may be biased or not estimable if the sampling points are not appropriately chosen, and 2) the inferences may be affected by the choices of time points.

Merits and limitations of the aforesaid methods are briefly summarized in Table 1.

REGULATORY GUIDANCE

FDA Guidelines

As discussed previously, an important application of dissolution testing is to address issues related to post-marketing changes. Depending on the nature and extent of the changes, dissolution testing may and may not be needed or sufficient. To help sponsors, FDA guidance^[5] clearly defines extent of dissolution testing needed to support postapproval changes.

Nature of Product or Process Changes

Since 1995, the U.S. FDA has issued several guidelines concerning approval of solid oral dosage form generic drugs or drugs that have undergone post approval changes.^[2–7] In the guidances, both the type and level of change are defined, as shown in Table 2.

Depending on the level and type of change, detailed recommendations on CMC tests (in particular, dissolution testing), *in vitro* and *in vivo* studies, and the necessary documentation that support the change are provided. For detail please refer to relevant FDA guidance.

Table 1 Merits and limitation of current methods for dissolution profile comparison

Model	Approach	Advantage	Disadvantage
Independent	f_2	• Intuitive • Easy to calculate	• Lack of statistical justification
	MSD	• Does not rely on specific model • Account for variances and co-variances among observations	• Lack of statistical rigor
Dependent	Weibull	• Empirical	• Model parameters may not be estimable or estimates are biased
	Exponential	• Permit specification of covariance structure	• Inferences may depend on time points
	Probit		
	Gompertz		
	Logistic		
	Higuchi	• Mechanistic	• Model parameters may not be estimable or estimates are biased
	Korsmeyer-Peppas	• Permit specification of covariance structure	• Inferences may depend on time points
	Hixson-Crowell		

Dissolution Testing Based on Biopharmaceutical Classification System

The extent of dissolution testing required by regulatory agencies depends on the solubility, permeability, dissolution, and pharmacokinetics of the drug product. The Biopharmaceutics Classification System (BCS), originally proposed by Amidon et al.^[25] adopted by the FDA, classifies drug substances into four groups based on solubility and permeability, as shown in Table 2. The objective of the BCS is to define the conditions under which an *in vitro* - *in vivo* correlation (IVIVC) is expected. In a 1997 FDA guideline^[3], IVIVC is defined as “[a] predictive mathematical model describing the relationship between an *in vitro* property of an extended release dosage form (usually the rate or extent of drug dissolution or release) and a relevant *in vivo* response, e.g., plasma drug concentration or amount of drug absorbed.” When an IVIVC is established, the dissolution test may be used as a surrogate for *in vivo* studies for certain scale-up and post approval changes, reducing the number of bioequivalence studies

required. Table 3 lists the four BCS classes and, their associated IVIVC expectations.

The FDA guidance presents a comprehensive perspective on 1) methods of developing an IVIVC and evaluating its predictability; 2) using an IVIVC to set dissolution specifications; and 3) applying an IVIVC as a surrogate for *in vivo* bioequivalence when it is necessary to document bioequivalence during the initial approval process, scale-up, or because of certain pre- or post-approval changes.

Dissolution Test Specifications

FDA 1997 guidance^[4] describes three categories of dissolution test specifications for immediate release drug products, along with their intended purposes. They are summarized in Table 4.

Dissolution Profile Comparison

FDA guidance^[3] requires that dissolution profile comparisons be carried out using model independent or model

Table 2 Levels and types of changes

Change	Description	
Level	1	Changes that are unlikely to have any detectable impact on formulation quality and performance
	2	Changes that could have a significant impact on formulation quality and performance
	3	Changes that are likely to have a significant impact on formulation quality and performance
Type	1	Components and composition
	2	Site of manufacture
	3	Scale of manufacture
	4	Manufacturing process and equipment

Table 3 Biopharmaceutical classification

Class	Solubility	Permeability	IVIVC expectation
I	High	High	IVIV correlation if dissolution rate is slower than gastric emptying rate. Otherwise, limited or no correlation is expected
II	Low	High	IVIV correlation expected if <i>in vitro</i> dissolution rate is similar to <i>in vivo</i> dissolution rate, unless dose is very high
III	High	Low	Absorption is rate-determining and limited or no IVIV correlation with dissolution rate
IV	Low	Low	Limited or no IVIV correlation expected

Table 4 Categories of dissolution test specifications

Type	Purpose
One point	As a routine quality control test (for highly soluble and rapidly dissolving drug products)
Two-point	- For characterizing the quality of the drug product - As a routine quality control test for certain types of drug products (e.g., slow dissolving or poorly water soluble product like carbamazepine)
Dissolution profile	- For accepting product sameness under SUPAC-related changes - To waive bioequivalence requirements for lower strengths of a dosage form

dependent methods. Descriptions of the methods noted in the guidance are provided in Table 5.

In the FDA 1997 guidance for SUPAC-MR: Modified Release Solid Oral Dosage Forms,^[5] the similarity factor f_2 is specifically recommended along with the requirement that the average difference at any dissolution sampling time point should not be greater than 15% between the pre- and post-change products, though other model independent or model-dependent methods can also be used. In addition, it is also stated that an f_2 value below 50 does not necessarily indicate lack of similarity, though

if $f_2 < 50$ a justification needs to be submitted to substantiate a similarity claim.

Differences between FDA and Other Regulatory Guidelines

As with the FDA, use of f_2 to assess profile similarity is recommended by the European Medicines Agency (EMA),^[8] again with similarity declared if $f_2 > 50$. However, EMA specifies that for calculation of f_2 , the following conditions need to be met: 1) a minimum of three time points (excluding zero) are needed; 2) the time points should be the same for the reference and test products; 3) twelve (12) individual values are required for every time point; 4) there can be no more than one mean value of $> 85\%$ dissolved; and 5) the coefficient of variation (CV) should be less than 20% for the first time point and less than 10% for all subsequent time points. If more than 85% of the drug is dissolved within 15 minutes for both products, dissolution profiles may be accepted as similar without further mathematical evaluation. Whereas the FDA guidance states that model-dependent methods can be used for dissolution profile similarity assessment, the EMA guideline makes no explicit mention of methods other than f_2 .

As noted by Diaz et al.,^[26] there has been a proliferation of divergent similarity requirements from regulatory authorities around the world. The differences not only reside in statistical considerations but also aspects of *in vitro* dissolution testing study design, such as the minimum

Table 5 Test procedures for dissolution comparison for immediate release solid oral dosage forms

Method Type	Conditions	Description
Model-Independent	f_2 Within batch variation $\leq 15\%$	- Estimate f_1 and f_2 - Similarity is claimed if $f_1 \leq 15$ and $f_2 > 50$
	MSD Within batch variation $> 15\%$	- Estimate MSD between test and reference mean dissolutions - Estimate 90% CI of true MSD - Similarity is achieved if the upper limit of the 90% CI is no larger than the similarity limit
Model-Dependent		- Select the most appropriate model and fit the data to the model Calculate MSD in model parameters and 90% CI of the true MSD - Similarity is achieved if the upper limit of the 90% CI is no larger than the similarity limit

number of time points and selection of the last time point, as well as a maximum %CV at individual time points. For example, FDA requires a minimum of three time points excluding zero but the Brazilian regulatory authority recommends five time points (excluding zero).

CRITIQUES OF CURRENT MODEL-INDEPENDENT METHODS

Requirements for Statistical Tests

Various critiques of the statistical approaches described above for demonstrating similarity for *in vitro* dissolution profiles have appeared in the literature. Thoughtful consideration was provided by Eaton et al.,^[27] who defined two normative requirements (NR) for a statistically rigorous dissolution profile similarity test:

- NR1: A specified function of the population parameters (not involving data) should be used to define dissolution profile similarity.
- NR2: No matter what testing procedure is used, there needs to be sufficiently detailed knowledge about the power function to allow and assessment of the probabilities of Type I and Type II errors.

NR 1 ensures that the assessment of dissolution profile similarity can be made using statistical hypothesis testing. NR 2 warrants that the performance of the test procedure can be evaluated. Three additional NRs were suggested by LeBlond et al.^[28] as follows:

- NR3: The parametric definition of similarity should be independent of the statistical methodology used to test for similarity.
- NR4: The test for similarity should make clear the inference space for the conclusion. For instance, does the conclusion apply to the populations of test and reference batches or only to those batches providing data for the comparison?
- NR5: A minimum confidence level should be included which properly accounts for estimation errors.

Taken together, these requirements can be used to assess the validity of statistical test procedures for dissolution profile comparison.

Statistical Issues with f_2 and MSD

f_2 Statistic

As originally described by Moore and Flanner,^[1] the f_2 acceptance criterion was defined in terms of the observed data. The similarity criterion of $f_2 > 50$, was justified on the basis that it corresponded to a constant difference of

10 between the observed test and reference results, which seems intuitively reasonable when test and reference dissolution profiles are parallel. This definition provided an easily calculated statistic and decision criterion. Dissolution similarity tests using f_2 have thus been conducted for the past two decades without consideration of underlying population parameters or other modeling considerations, such as correlation among the response measured at different time points. The use of f_2 has been criticized on this and other bases by various authors. Most problematic is that it lacks statistical justification, as it does not meet any of the above normative requirements. It is likely $f_2 > 50$ while the two dissolution profiles are dissimilar, and vice-versa.^[29]

MSD

FDA agencies provide for the use MSD in cases where the dissolution measurement is highly variable. The MSD approach is an improvement over the current practice using f_2 as recommended in guidance documents. First, MSD does rely on an underlying statistical model. Second, the MSD takes into account variances and covariances among the different dissolution time points, whereas f_2 does not. However, there is no recommended decision criterion for MSD as there is with f_2 . While some researchers have proposed similarity criteria for MSD or MSD-like statistical procedures, there currently is no industry standard and users of MSD are left to justify their own criteria for similarity.

ALTERNATIVE METHOD

Over the last decade, the importance of risk-based decision making in the pharmaceutical industry has been increasingly emphasized by global regulatory agencies. Risk-based decisions oftentimes require an assessment of decision error probabilities, thus proper statistical modeling of the underlying data-generation mechanism. To align dissolution similarity practice with current regulatory thinking, it seems imperative to introduce additional statistical rigor into dissolution similarity comparisons. A first step in this direction could be to re-define the f_2 “fit factor” parametrically. To this end, Novick et al.^[30] introduced the parametric function F_2 .

Model

In the following discussion, the problem of interest is to compare the dissolution from a single reference batch with those from a single test batch. Let $Y_{br} = (Y_{b1r}, Y_{b2r}, \dots, Y_{bpr})^T$ be the vector of dissolution measurements from vessel r ($r = 1, 2, \dots, R$) from batch b ($b = \text{reference, test}$) at time points t_p , $i = 1, 2, \dots, k$. It is assumed that

$$Y_{br} = \mu_b + \epsilon_b$$

where $\mu_b = (\mu_{b1}, \mu_{b2}, \dots, \mu_{bk})^T$ is the mean of Y_{br} and ϵ_b is the vector of measurement errors, Y_{br} and ϵ_b following a multi-variate normal distribution, $N(\mu_b, V_b)$.

The structure of the variance-covariance matrices V_b may take on various forms, allowing for modeling potential correlations among measurements taken at different time points. For instance, if Y_{br} follows an auto-regressive model AR(1), V_b may be expressed as $(\sigma^2 \rho^{|i-j|})$. Table 6 lists some examples from SAS/STAT 9.2 User's Guide.^[31]

It is worth noting that the variance can also be modeled as a function of the mean. For example, one may use $\text{Var}(Y_{br}) = \sigma_1^2 + \sigma_2^2(|\mu_{br}/100|)(|1 - \mu_{br}/100|)$ to capture the relationship between the mean response values and corresponding variances at various time points. One may also assume $V_{\text{Reference}} = V_{\text{Test}}$ if supported by historical data, which simplifies model fitting.

Hypotheses for Dissolution Profile Comparison

Novick et al.^[30] suggested establishing dissolution profile similarity through testing the following hypotheses:

$$H_0: \left| \mu_{\text{Ref},t} - \mu_{\text{Test},t} \right| \geq 15 \text{ for some } t = 1, 2, \dots, k \text{ OR } F_2 \leq 50$$

$$H_a: \left| \mu_{\text{Ref},t} - \mu_{\text{Test},t} \right| < 15 \text{ for all } t = 1, 2, \dots, k \text{ AND } F_2 > 50$$

Bayesian Test Procedure

Novick et al.^[30] also suggested a Bayesian procedure for testing the above hypotheses. Let

$$\delta(p) = \max_{t=1, \dots, k} \left| \mu_{\text{Ref},t} - \mu_{\text{Test},t} \right| \text{ and}$$

$$q = \Pr(\delta(k) < 15 \text{ and } F_2 > 50 | \text{data})$$

A decision can be made to accept H_a if $q > q_0$, where q_0 is a pre-specified value between 0 and 1 but close to 1; otherwise H_0 is accepted. Calculation of the above probability can be carried out in a couple of ways: 1) If the joint posterior distribution of the model parameters can be analytically derived, the probability in (4) can be estimated by simulating random samples from the posterior distribution and calculating the percent of simulated samples for which the conditions $\delta(k) < 15$ and $F_2 > 50$ are met; or 2) when a closed-form solution for the posterior distribution is unavailable, the Markov Chain Monte

Carlo (MCMC) method can be used to estimate the probability q . This method indirectly draws random samples from the joint posterior distribution by constructing a Markov chain that has the joint posterior distribution as its limiting distribution. The MCMC method can be computationally intensive, however with the availability of MCMC software packages such as OpenBUGS,^[32] JAGS,^[33] and SAS Proc MCMC^[31], the computations can be readily carried out.

The use of a Bayesian approach for assessing dissolution similarity has several advantages. First, it allows for incorporating the uncertainty in the model parameters in the posterior probability calculation. Second, it provides a level of assurance to the similarity claim by way of calculating posterior probability for meeting the similarity acceptance criteria. Third, the availability of MCMC software packages makes it more straightforward to make statistical inferences about functions of model parameters when compared to frequentist methods. Lastly, Bayesian inference is not as limited by small amounts of data as the frequentist methods are.

Posterior Distribution

Let $Y_b = (Y_{b1}, Y_{b2}, \dots, Y_{bk})$, $\bar{Y}_b = R^{-1} \sum_{r=1}^R Y_{br}$, and $S_b^2 = \sum_{r=1}^R (Y_{br} - \bar{Y}_b)(Y_{br} - \bar{Y}_b)^T$. Consider the parameters μ_b and V_b to follow the conjugate prior distributions:

$$\mu_b | V_b \sim N(\mu_0, V_b / k_0)$$

$$V_b \sim \text{IW}(\Lambda_0^{-1}, \nu_0)$$

where μ_0 , k_0 , Λ_0^{-1} , and ν_0 are hyper-parameters, of the Normal and inverse Wishart distributions. It is well-known that

$$V_b | Y_b \sim \text{IW}(\Lambda_R^{-1}, \nu_R)$$

$$\mu_b | (V_b, Y_b) \sim N(\mu_R, V_b / k_R),$$

where $\nu_R = \nu_0 + R$, $k_R = k_0 + R$, $\nu_R = \nu_0 + S_b^2 + \left(\frac{k_0 R}{k_0 + R} \right) (\bar{Y}_b - \mu_0)(\bar{Y}_b - \mu_0)^T$, and

$$\mu_R = \left(\frac{k_0}{k_0 + R} \right) \mu_0 + \left(\frac{R}{k_0 + R} \right) \bar{Y}_b.$$

Table 6 Some examples of covariance structures

Covariance Structure	Covariance Element	Description
AR(1)	$\sigma^2 \rho^{ i-j }$	Equally-spaced time points, homogeneous variance
ARH(1)	$\sigma_i \sigma_j \rho^{ i-j }$	Equally-spaced time points, heterogeneous variance
SP(POW)	$\sigma^2 \rho^{ t_i - t_j }$	Unequally-spaced time points
UN	σ_{ij}	Unstructured

With a Jeffrey's prior ($k_0 = 0$, $\nu_0 = -1$, $|A_0| = 0$), samples from the posterior distribution may be drawn with $\Lambda_R = S_b^2$ and $\mu_R = \bar{Y}_b$ with $\nu_R = R-1$ and $k_r = R$. Assuming that $V_{\text{Ref}} = V_{\text{Test}} = V$, the posterior distributions are:

$$V | Y_b \sim \text{IW}(\Lambda_R^{-1}, \nu_0 + 2R)$$

$$\mu_b | (V, Y_b) \sim N(\mu_R, V / k_r),$$

where $\Lambda_R = \Lambda_0 + \sum_b \left\{ S_b^2 + \left(\frac{k_0 R}{k_0 + R} \right) (\bar{Y}_b - \mu_0)(\bar{Y}_b - \mu_0)^T \right\}$,

and $\mu_R = \left(\frac{k_0}{k_0 + R} \right) \mu_0 + \left(\frac{R}{k_0 + R} \right) \bar{Y}_b$. With a Jeffrey's prior, samples from the posterior distribution may be drawn with $\Lambda_R = \sum_b S_b^2$ and $\mu_R = \bar{Y}_b$ with $\nu_R = 2R-2$ and $k_r = R$.

For dissolution profile comparisons, other prior distributions than the ones described above may be used, if appropriate, based on knowledge of the model parameters. It is worth pointing out that use of the inverse Wishart distribution as a prior for V_b has been criticized for being too sensitive to the chosen degrees of freedom.^[34] In the literature, several remedies such as the scaled inverse Wishart have been proposed.^[34,35] For example, Gelman and Hill^[35] method begins with decomposing the covariance matrix into the form:

$$\Sigma = \text{Diag}(\xi) \mathbf{Q} \text{Diag}(\xi),$$

where $\text{Diag}(\xi)$ and $\mathbf{Q}$ are diagonal and correlation matrices, respectively. Such an re-expression of the covariance matrix makes it possible assign priors to the variances and correlation separately.

The use of prior information is a critical step in statistical inference based on a posterior distribution, and the selection of prior distributions has been much discussed in the literature. An informative prior may be established from early experiments, which may render more power for the test procedures than the use of non-informative priors. In the absence of relevant data, subjective prior information from expert opinions may be used.

Example

In the following example, we illustrate the use of the Bayesian method discussed above, using one of the four examples by Novick et al.^[30] The AR(1) covariance structure in Table 6 is assumed with $\sigma^2 = 6.25$ and $\rho = 0.4$, respectively. It is further assumed that the test and reference products were tested at times 15, 30, 45, 60, and 75 minutes, with 12 vessels tested at each time point. The mean values at each time point are provided in Table 7; the dissolution profiles are shown in Fig. 2. The posterior probability q previously defined was calculated for three choices of prior distributions: 1) Jeffrey's prior; 2) Scaled inverse Wishart

with $\mu_{\text{bt}} \sim N(50, 30^2)$, diagonal elements of $\text{Diag}(\xi)$ equal to $U(0, S_i)$ where S_i is a frequentist upper 99% confidence limit for the i^{th} diagonal element of V , and $\mathbf{Q} \sim \text{IW}(\mathbf{I}, p+1)$, where $\mathbf{I}$ is the identity matrix; and 3) AR(1) with $\mu_{\text{bt}} \sim N(50, 30^2)$, $\sigma \sim U(0, 100)$ and $\rho \sim U(0, 1)$.

For the Jeffrey's prior, twenty thousand (20,000) independent posterior samples were drawn. For the scaled inverse Wishart and AR(1) priors, four independent chains were run in OpenBUGS, each with burnin = 5,000 and posterior samples = 10,000 after thinning by 25, for a total of 40,000 posterior draws; effective sample sizes for all parameters were above 35,000. From the model parameters, posterior distributions for F_2 and $\delta(p)$ were generated and posterior probabilities were calculated for $\Pr(F_2 > 50)$, $\Pr(\delta(p) < 15)$ and $q = \Pr(\delta(p) \text{ and } F_2 > 50)$.

The true values, based on the true dissolution profiles, were $F_2 = 51.3$ (pass) and $\delta(p) = 16$ (fail). For this data set, the observed statistic $f_2 = 52.3$, from which one would declare that the two dissolution profiles are similar using the FDA-recommended approach, yet one of the

Fig. 2 Dissolution profiles from the simulated example. The response represents percent of dissolution (adapted from Novick et al.^[30])

Table 7 Means and mean differences at each time point for reference and test batches

Time (minute)	Reference	Test	Difference
15	30	30	0
30	50	48	2
45	64	58	6
60	72	60	8
75	76	60	16

mean differences between batches is quite high (=16%); thus, adding the criterion on $\delta(p)$ provides some protection against declaring in such a scenario. The results from the Bayesian analyses using the three prior-distribution methods were all similar; the results are provided in Table 8.

Because the data were generated with an AR(1) covariance structure, it is reasonable to expect that the AR(1) assumption in the posterior sampling would result in more precise estimates of the parameters than the other choices of priors. From the three data examples in section 2, it appears that the three choices of priors result in similar performance.

DISCUSSION

Dissolution testing is an important component of pharmaceutical development. It can be used for guiding the development of new formulations, monitoring drug product lot-to-lot quality, and ensuring drug product performance after certain post approval changes. Despite the importance of dissolution testing, there are inconsistencies in regulatory requirements for dissolution testing and dissolution similarity profile comparisons. Although the f_2 similarity factor approach suffers many deficiencies, it is recommended by many regulatory authorities for assessing dissolution profile similarity. Likewise, despite lack of statistical robustness, the MSD method is also adopted by some regulatory agencies including FDA.

This article provides an overview of regulatory requirements for dissolution similarity assessment, critiques of the f_2 and MSD approaches, and discussion of published statistical methods proposed as remedies for the deficiencies of the f_2 and MSD methods. A Bayesian alternative for dissolution profile comparisons is presented in detail, which is intended to be an improvement over current methods. The Bayesian approach not only accounts for uncertainties in unknown parameters, but also allows for the incorporation of correlations among responses measured at different time points. The approach can be easily implemented through the use of Bayesian MCMC simulation. As pointed out by Novick et al. (2015), the approach can be extended in two aspects: one is to compare dissolution profiles which are

measured in a continuous temporal manner and the other is to quantify dissolution equivalences for two processes based on dissolution testing of multiple batches from each process. For the latter, one would need to use a hierarchical model which contains effects that represent batch-to-batch variations.

ACKNOWLEDGEMENT

The author would like to thank Ms. Katherine Giacoletti and Dr. Lorin Roskos for their helpful review of the article.

Dissolution Profiles Comparison: Model-Independent Approaches

Yanbing Zheng and Lanju Zhang

Data and Statistical Sciences, AbbVie Inc., North Chicago, Illinois, U.S.A.

Abstract

Dissolution profiles comparison has become an important regulatory requirement for drug manufacturing process changes and has received intensive scientific interests in pharmaceutical industry. In this entry, we review the model-independent approaches based on multivariate statistical distance tests to test the similarity between dissolution profiles and evaluate their operating characteristics through a simulation study.

Keywords: Dissolution profile; Equivalence; Model-independent approaches; Multivariate statistical distance; Similarity.

INTRODUCTION

Dissolution profile of a drug product describes its release pattern under certain specified conditions. Compared to a single-point dissolution test, dissolution profile characterizes the drug product more completely. Comparison between dissolution profiles is performed when a change takes place in, for instance, scale of manufacture, manufacturing site, component and composition, equipment, and process.^[1] Dissolution profiles comparison is important in understanding the effect of manufacturing process changes on drug quality.

In general, the methods for dissolution profiles comparison can be categorized into three groups: 1) model-dependent methods; 2) model-independent methods based on a similarity factor; and 3) model-independent methods using multivariate statistical distance (MSD) tests.^[2] A model-dependent approach models dissolution profiles through mathematical functions and considers the time variable as a predictor to the amount (percentage) dissolved. For example, Langenbucher^[3] proposed to use Weibull distribution to characterize the dissolution rate curve, which is flexible in describing a wide variety of dissolution profile shapes. Alternatively, other mathematical models such as the first-order kinetic model, Hixson–Crowell model, Higuchi model, probit function, exponential function, Gumpertz function, and logistic function have been studied in literature to fit dissolution data (refer, e.g., literatures^[4–7]).

The U.S. Food and Drug Administration (FDA) guidance for industry on dissolution testing of immediate release solid oral dosage forms^[8] provides a model-independent approach using a similarity factor (f_2), which was proposed by Moore and Flanner.^[9] The similarity factor f_2 is defined as:

$$f_2 = 50 \times \log_{10} \left\{ \left[1 + (1/T) \sum_{t=1}^T (R_t - T_t)^2 \right]^{-0.5} \times 100 \right\} \quad (1)$$

where T is the number of dissolution sample time points and R_t and T_t are the mean percent dissolved at each time point, t , for the reference and test dissolution profiles, respectively. FDA guidance suggests using only one measurement after 85% dissolution of both products. When the two profiles are identical, $f_2 = 100$. An average difference of 10% at all measured time points results in an f_2 value very close to 50. FDA has suggested an f_2 value between 50 and 100 to indicate similarity between two dissolution profiles.

The factor f_2 measures the closeness between two profiles with emphasis on the larger difference among all time points and is referred to as a similarity factor. The f_2 approach is the simplest approach for dissolution profiles comparison. However, this criterion only takes into account the sample mean difference at sampled time points without incorporating the variation information in the dissolution data. As a result, the FDA guidance recommends that, to implement the f_2 approach, the percent coefficient of variation at the earlier time points should not be more than 20%, and at other time points should not be more than 10%. A multivariate model-independent procedure is suggested when one of these two requirements fail. LeBlond et al.^[2] gives a detailed discussion of the deficiencies of the f_2 approach.

In this entry, we focus on model-independent MSD test approaches. These approaches rely on the assumption of multivariate normality of amount (%) of drug release at sampled time points and consider different distance measurements to quantify the similarity between

the two dissolution profiles. In section “Model-Independent MSD Methods for Dissolution Profile Comparison,” we review three model-independent MSD approaches—two Hotelling’s T^2 -based approaches developed by Tsong et al.^[10] and Saranadasa,^[11] respectively, and a two one-sided test (TOST)-based approach developed by Saranadasa and Krishnamoorthy.^[12] In section “Simulation Study,” we perform simulation studies to compare the performance of the three methods under different scenarios, followed by section “Discussion and Conclusions.”

MODEL-INDEPENDENT MSD METHODS FOR DISSOLUTION PROFILE COMPARISON

Hotelling’s T^2 -Based Approaches

Suppose $x_{ij} \sim N_p(\mu_i, \Sigma)$, where i denotes the population number, $i = 1, 2$, j is the replicate number, $j = 1, 2, \dots, n_i$, and p is the number of time points that are measured. Note that x_{1j} and x_{2j} are p -dimensional random vectors with the same covariance matrix, Σ . The sample mean vector and covariance matrix for each profile are denoted as $\bar{x}_i$ and S_i , respectively. The pooled covariance matrix, an estimate of Σ , is:

$$S_{\text{pooled}} = \frac{(n_1 - 1)S_1 + (n_2 - 1)S_2}{n_1 + n_2 - 2} \quad (2)$$

The null hypothesis based on Hotelling’s T^2 is $H_0: \mu_1 - \mu_2 = \mu$. The $(1 - \alpha)100\%$ confidence region of the true mean difference μ can be derived from:

$$T^2 = (\bar{x}_1 - \bar{x}_2 - \mu)' \left[\left(\frac{1}{n_1} + \frac{1}{n_2} \right) S_{\text{pooled}} \right]^{-1} (\bar{x}_1 - \bar{x}_2 - \mu) \leq \frac{(n - 2)p}{(n - p - 1)} F_{p, n-p-1}(\alpha) \quad (3)$$

where $F_{p, n-p-1}(\alpha)$ is $(1 - \alpha)100\%$ percentile of the central F distribution with p and $n - p - 1$ degrees of freedom with $n = n_1 + n_2$.

Tsong et al.^[10] proposed to use the Mahalanobis distance^[13] to measure the similarity of two dissolution profiles:

$$D_M = \sqrt{(\bar{x}_1 - \bar{x}_2)' S_{\text{pooled}}^{-1} (\bar{x}_1 - \bar{x}_2)} \quad (4)$$

Using the Lagrange multipliers approach, they calculated the $(1 - \alpha)100\%$ confidence limit of the true distance:

$$D_M^\mu = \sqrt{\mu' S_{\text{pooled}}^{-1} \mu} \quad (5)$$

based on the confidence region of μ (Eq. 3) and compared the confidence limit of true D_M^μ with the tolerance limit

$\sqrt{\theta^2 J_p' S_{\text{pooled}}^{-1} J_p}$ for equivalence determination, where θ is the difference specified as the global similar limit and J_p is a vector of 1s. Tsong et al.^[10] suggested to specify the similarity limit taking into account the variation of dissolution data.

Alternatively, Saranadasa^[11] assumed the parallelism of the two dissolution profiles and then derived the maximum mean difference d , for which the two dissolution profiles can be declared equivalent with $(1 - \alpha)100\%$ confidence. Based on the confidence region (Eq. 3), d is the solution to the equation:

$$T^2 = (\bar{x}_1 - \bar{x}_2 - dJ_p)' \left[\left(\frac{1}{n_1} + \frac{1}{n_2} \right) S_{\text{pooled}} \right]^{-1} (\bar{x}_1 - \bar{x}_2 - dJ_p) = \frac{(n - 2)p}{(n - p - 1)} F_{p, n-p-1}(\alpha) \quad (6)$$

The closed expression for d can be obtained as follows. By solving:

$$T_0^2 = (\bar{x}_1 - \bar{x}_2)' \left[\left(\frac{1}{n_1} + \frac{1}{n_2} \right) S_{\text{pooled}} \right]^{-1} (\bar{x}_1 - \bar{x}_2) = \frac{(n - 2)p}{(n - p - 1)} F_{p, n-p-1, \lambda}(\alpha) \quad (7)$$

for λ , the non-centrality parameter, the maximum mean distance can be calculated as:

$$d = \left[\frac{\lambda n(n - 2)}{(n - p - 3)n_1 n_2 \text{sum}(S_{\text{pooled}}^{-1})} \right]^{\frac{1}{2}} \quad (8)$$

where $\text{sum}(S_{\text{pooled}}^{-1})$ is the sum of the elements of S_{pooled}^{-1} . If,

$$T_0^2 < \frac{(n - 2)p}{(n - p - 1)} F_{p, n-p-1}(\alpha) \quad (9)$$

then d is defined as 0. When the estimated maximum mean distance, d , is less than a prespecified threshold, d_0 , the two dissolution profiles are deemed equivalent. The threshold, d_0 , depends on the confidence level. With a 90% confidence level, Saranadasa^[11] suggests $d_0 = 6\%$.

Saranadasa and Krishnamoorthy’s (SK) Method

The SK multivariate method used to determine the equivalence of two dissolution profiles is described in the study by Saranadasa and Krishnamoorthy.^[12] Similar to Saranadasa,^[11] the SK method assumes the parallelism of two dissolution profiles. Let $\bar{x}_d = \bar{x}_1 - \bar{x}_2$ follow a multivariate normal distribution:

$$\bar{x}_d \sim N_p \left(\delta J_p, \Sigma \left(\frac{1}{n_1} + \frac{1}{n_2} \right) \right) \quad (10)$$

where δ is a constant. Consider the hypotheses:

$$H_0: \delta > \delta_0 \text{ or } \delta < -\delta_0 \text{ versus } H_A: -\delta_0 \leq \delta \leq \delta_0 \quad (11)$$

If H_A is true, then the dissolution profiles are deemed equivalent. Following the description in the study by Saranadasa and Krishnamoorthy,^[12] δ can be estimated as:

$$\hat{\delta} = \frac{J_p' S_p^{-1} \bar{x}_d}{J_p' S_p^{-1} J_p} \quad (12)$$

H_0 is rejected if:

$$P_1 = P\left(t_{n-p-1} > \frac{\hat{\delta} + \delta_0}{SE}\right) < \alpha \text{ and} \\ P_2 = P\left(t_{n-p-1} < \frac{\hat{\delta} - \delta_0}{SE}\right) < \alpha \quad (13)$$

or

$$p \text{ value} = \max\{P_1, P_2\} < \alpha \quad (14)$$

where SE is the standard error of $\hat{\delta}$ and is calculated as described in the study by Saranadasa and Krishnamoorthy.^[12] This test is known as a TOST.^[14,15] This α level test is equivalent to calculating a $(1 - 2\alpha)100\%$ confidence interval for δ and checking that the interval is contained in $(-\delta_0, \delta_0)$.

Saranadasa and Krishnamoorthy^[12] recommended using $\delta_0 = 10\%$ with $\alpha = 0.05$. If $\delta = 10\%$, then the similarity factor f_2 is approximately 50%, which is the threshold recommended by the FDA guidance^[8] for the comparison procedure.

SIMULATION STUDY

A simulation study is conducted to evaluate the performance of the three model-independent MDS approaches. We assume the dissolution profile of a drug multivariate distribution tablet measured at four time points ($p = 4$) follows a multivariate normal distribution with a covariance matrix following the compound symmetry heterogeneous structure:

$$\begin{bmatrix} \sigma_1^2 & \rho\sigma_1\sigma_2 \cdots & \rho\sigma_1\sigma_p \\ \vdots & \ddots & \vdots \\ \rho\sigma_1\sigma_p & \rho\sigma_2\sigma_p \cdots & \sigma_p^2 \end{bmatrix} \quad (15)$$

We consider the cases where $\rho = 0$ and $\rho = 0.5$, $(\sigma_1, \sigma_2, \sigma_3, \sigma_4) = (10, 10, 5, 5)$, $(\sigma_1, \sigma_2, \sigma_3, \sigma_4) = (5, 5, 5, 5)$

and $(\sigma_1, \sigma_2, \sigma_3, \sigma_4) = (2, 2, 2, 2)$. Dissolution profiles for 12 tablets ($n_1 = n_2 = 12$) are generated, respectively, for a reference batch and a test batch. Regarding the selection of similarity limit, we use $\theta = 10\%$ as suggested in the study by Tsong et al.,^[10] $d_0 = 6\%$ as suggested in the study by Saranadasa^[11] and $\delta_0 = 10\%$ as suggested in the study by Saranadasa and Krishnamoorthy.^[12]

We evaluate the performance of MDS approaches with/without the parallelism assumption of two dissolution profiles satisfied. For the cases where the parallelism assumption is not satisfied, we consider the scenarios with parallelism assumption marginally satisfied $\mu_1 - \mu_2 = \mu = (10, 10, 3, 3)$, $\mu_1 - \mu_2 = \mu = (20, 10, 3, 3)$, and parallelism assumption completely failed $\mu_1 - \mu_2 = \mu = (40, 20, 10, 3)$. A total of 1000 simulation runs were conducted under each simulation setting and the probability of claiming equivalence for each method was reported.

Figs. 1–3 show the simulation results when the assumption of parallelism between two dissolution profiles is satisfied. From the figures, we can see that the type I error rate of the SK method is roughly controlled at 0.05 while the f_2 method is very liberal. The Hotelling's T^2 -based method proposed in the study by Tsong et al.^[10] is relatively conservative especially when the variance of dissolution data is large. Another Hotelling's T^2 -based method proposed in the study by Saranadasa^[11] is liberal when the dissolution data have large variance and relatively conservative when the variance is small.

Tables 1–4 show the simulation when the assumption of parallelism between two dissolution profiles is not satisfied. When the two dissolution profiles are partially dissimilar or dissimilar [$\mu = (20, 10, 3, 3)$ or $\mu = (40, 20, 10, 3)$ in the simulation study], the f_2 factor and the approach proposed by Tsong et al.^[10] have good performance on not claiming equivalence. However, the approach proposed in the study

Fig. 1 The probability of claiming equivalence for the simulation setting with constant mean difference between dissolution profiles ($\mu_1 - \mu_2 = \mu = \delta J_4$), $\sigma_1, \sigma_2, \sigma_3, \sigma_4 = (10, 10, 5, 5)$, and $\rho = 0.5$

Fig. 2 The probability of claiming equivalence for the simulation setting with constant mean difference between dissolution profiles ($\mu_1 - \mu_2 = \mu = \delta J_4$), $(\sigma_1, \sigma_2, \sigma_3, \sigma_4) = (5, 5, 5, 5)$, and $\rho = 0.5$

Fig. 3 The probability of claiming equivalence for the simulation setting with constant mean difference between dissolution profiles ($\mu_1 - \mu_2 = \mu = \delta J_4$), $\sigma_1, \sigma_2, \sigma_3, \sigma_4 = (2, 2, 2, 2)$, and $\rho = 0.5$

SK, $\delta_0 = 10\%$	0.968	0.142	0

by Tsong et al.^[10] could be very conservative when the variance of dissolution data is large. The SK method and the approach in the study by Saranadasa^[11] could incorrectly result in high probability of claiming equivalence especially when there is relatively high variation in dissolution data and high correlation between time points. Relatively, the f_2 approach has good power of claiming equivalence and good type I error control.

DISCUSSION AND CONCLUSIONS

The model-independent approaches for dissolution profile comparison using MSD tests developed in the studies by

Tsong et al.,^[10] Saranadasa,^[11] and Saranadasa and Krishnamoorthy,^[12] take into account the mean difference between dissolution profiles while adjusting for the covariance structure of dissolution data. They are all equivalence test approaches with prespecified tolerance limits. But the literature implementations of the MSD test methods have been controversial.^[2]

According to the simulation study, when the parallelism assumption is satisfied, the SK method has relatively good power of claiming equivalence with type I error under control. However, this method fails when the parallelism assumption is not satisfied. The performance of the method in the study by Saranadasa^[11] is highly affected by the covariance structure of dissolution data. The method proposed in the study by Tsong et al.^[10] is relatively conservative. The f_2 method recommended by FDA has good power to determine similarity but it could be very liberal when the two dissolution profiles are parallel. The performance of these methods is not satisfying and more research is needed for better approaches.

Dosage Units Using Small and Large Sample Sizes: Uniformity

Meiyu Shen and Yi Tsong

Center for Drug Evaluation and Research, U.S. Food and Drug Administration,
Silver Spring, Maryland, U.S.A.

Abstract

The purpose of uniformity of dosage unit test is to determine the degree of uniformity in the amount of drug substance among dosage units in a batch. Content uniformity test is based on the assay of the individual content of drug substance(s) in a number of dosage units. Content uniformity test is required by the regulatory authorities such as US Food and Drug Administration to confirm that the unit dose of a drug product is consistent with the label claim. Although USP <905> is not intended for batch releases as it is clearly declared in the general notices and requirements of the USP pharmacopeia, many pharmaceutical companies still propose to implement USP <905> as their batch release specification. We present the details of USP <905> and propose a two one-sided parametric tolerance interval for small samples. We also present the details of parametric and nonparametric methods by European Pharmacopoeia 8.1 and propose a parametric tolerance interval method for large samples. Furthermore, we discuss the performances of these acceptance sampling plans.

Keywords: Compendia test; Content uniformity; Counting test; Tolerance interval; Uniformity of dosage units.

INTRODUCTION

The purpose of the uniformity of dosage unit (UDU) test is to quantify the variability in the amount of drug substance between dosage units in a batch and to compare that variability to a corresponding specification.^[1,2] In this chapter, the main interest is to discuss the compendia UDU test and to develop a parametric UDU test for batch release. Dosage units are defined as dosage forms containing a single dose or a part of a dose of drug substance in each unit. In most cases, the UDU test measures the amount of drug substance contained within the unit (e.g., tablets and capsules). In some cases UDU measures the amount of drug delivered via a dose metering device component (e.g., metered dose inhalers abbreviated as MDIs). In these cases, the test is referred to as uniformity of delivered dose (UDD). In a few instances, both the UDU and UDD tests may apply to the same product. For example, in a dry powder inhaler (DPI) that uses individual capsules or blisters containing the formulation to be inhaled. In such cases, UDU testing is needed to control for the variability in the individual capsules or blisters, and UDD testing is needed to control for the delivered dose ex-device used for inhalation.

Content uniformity test is based on the assay of the individual content of drug substance(s) in a number of dosage units. Content uniformity test is required by the regulatory authorities such as US Food and Drug Administration to confirm that the unit dose of a drug product is consistent with the label claim. ICH guideline Q4B, Annex 6^[3] recommends that a Pharmacopeia procedure is used to assess the uniformity of dosage units. For example, the United States Pharmacopoeia (USP) publishes USP <905>.^[1] USP <905> is used in the United States, the European Union, and Japan as the harmonized content uniformity test based on tolerance interval and indifference zone concepts. Although USP <905> is not intended for batch releases as it is clearly declared in the general notices and requirements of the USP pharmacopeia, many pharmaceutical companies still propose to implement USP <905> as their batch release specification. Since USP <905> uses an indifference zone concept (M), USP <905> is biased in favor of off-target products. Here M is defined by the sample mean of the tested n dosage units, $\bar{X}$, as: $M = 98.5\%$ if $\bar{X} < 98.5\%$, $M = 101.5\%$ if $\bar{X} > 101.5\%$, and $M = \bar{X}$ otherwise. To address this issue, Tsong and Shen^[4] propose a parametric tolerance interval test (PTIT) to test a two-sided specification that is equivalent to the test of two one-sided hypotheses. Testing against a lower specification is to assure that the drug product is not under-dosed for the sake of efficacy. On the other hand, testing against an upper

This article represents only the authors' opinion and not necessarily the official position of the US Food and Drug Administration.

specification is to assure that the drug product is not overdosed for the sake of safety.

With the development of analytic technology such as near-infrared spectroscopy, testing on large sample sizes becomes feasible. As a compendia test, the USP <905>, a harmonized content uniformity test, has been developed for a small fixed sample size, and it provides no guidance on how to conduct the test at different sample sizes. There have been several proposals in the literature for content uniformity using large sample sizes. In 2006, Sandell, Vukovinsky, Diener, Hofer, Pazdan, and Timmermans^[5] proposed a one-tiered nonparametric test which counted the number of tablets with content outside (85%, 115%) LC. The batch complies if no more than c units are outside (85%, 115%) LC. They also provided values of c for a selection of potential sample sizes. This proposed counting test has operating characteristic (OC) curves intersecting with the OC curve of the USP <905> around 45% probability of accepting a batch with the batch mean of 100% LC in^[5] (see Figure 3). This counting test has been proposed as a batch-release test when a large number of dosage units are tested.

In 2010, Bergum and Vukovinsky^[6] proposed a modified version of the counting test by Sandell et al.^[5] They propose to set the integer part of $0.03 \times n$ equal to c^* , which is the acceptance limit for the maximum number of tablets outside (85%, 115%) LC, here n is the number of dosage units tested (For example, with $n = 260$, c^* is 7). Thus, a batch complies if the number of tablets outside (85%, 115%) LC is no more than c^* .

In 2012, the Council of Europe^[7] published two options for uniformity of dosage units using large sample sizes in European Pharmacopoeia 7.7. Option 1 is a parametric two-sided tolerance interval based method modified with an indifference zone and counting units outside of (0.75M, 1.25M). Recall M is a function of data defined above. Option 2 is a nonparametric counting method with an additional indifference zone concept. Option 2 in European Pharmacopoeia 7.7 was intended to revise the original proposal of large sample UDU test whose OC curve intersects with OC curve of USP <905> around 45% passing probability.^[8] However, mathematical and statistical methodologies to derive the revised Option 2 were not discussed in.^[8] It would result in an unanswered question how to determine $c1$ and $c2$ for sample sizes not included in Table 2.9.47.2.^[7]

In April 2014, the Council of Europe^[9] published the corrected version of EU Option 2 in which the indifference zone is removed for uniformity of dosage units using large sample sizes in European Pharmacopoeia 8.1. With Option 2, a batch is accepted if no more than $c1$ units lie outside (0.85T, 1.15T) and no more than $c2$ units lie outside (0.75T, 1.25T), where T is defined as 100. The counts $c1$ and $c2$ for the selected sample sizes are given in Table 2.9.47-2 of European Pharmacopoeia 8.1. European Pharmacopoeia 8.1 provides no explanation how the counts

were derived. But the counts $c2$ are almost identical to Option 1.

Note that the approaches described earlier provide some assurance that a batch passing the release test may comply with USP <905>, the content uniformity sampling test using small number of dosage units.

In 2014, Shen, Tsong, and Dong^[10] studied the statistical properties of the large sample tests for content uniformity. They propose a large sample acceptance sampling method based on parametric two one-sided tolerance intervals. In particular, this proposed method is designed to have its OC curve for any given sample size intersect with the OC curve of the harmonized USP <905> at the acceptance probability of 90% for a batch whose individual tablets follow normality with the mean of 100% LC. They denote this proposed method as PTIT_matchUSP90 method. They compare the acceptance probabilities of PTIT_matchUSP90 method with those of the two procedures recommended in European Pharmacopoeia 7.7 when the unit dose is assumed to be a continuous random variable, e.g., normal or mixture of normal distributions. They also show that with two one-sided tolerance intervals criteria, the proposed test can accept or reject a batch based on the percentage outside either 85% or 115% LC regardless the distribution is normal or not. Such statistical property assures high acceptance probability of samples from the same batch when repeatedly tested with USP <905>, a small sample size test, since OC curve (acceptance probability versus standard deviation) of PTIT_matchUSP90 for any sample size intersects with OC curve of USP <905> at 90% of acceptance probability when the batch mean is on the target (100% LC). OC curves of others^[5,6] intersect with OC curve of USP <905> at <90% (e.g., 45%) of acceptance probability provide low assurance that samples in a batch pass compendia standard when repeatedly subjected to USP<905> UDU acceptance sampling plan.

The structure of this chapter is arranged as follows. In Section 2, we present the details of USP <905> and PTIT of Tsong and Shen^[4] for small samples. We also present the details of EU Option 1 and EU Option 2 (the counting method) proposed in European Pharmacopoeia 8.1 and the PTIT_matchUSP90 method proposed by Shen, Tsong, and Dong for large samples^[10] since European Pharmacopoeia 8.1 is most updated version so far. In Section 3, we discuss the performance of USP <905> and PTIT for small samples and the performance of PTIT_matchUSP90 method, EU Option 1, and the EU Option 2.

ACCEPTANCE SAMPLING PLANS

In this section, we are going to present the details of USP <905> UDU acceptance sampling plan and PTIT method for dose content uniformity using small sample sizes and then present the details of EU Option 1, EU Option 2, and

PTIT_matchUSP90 for UDU acceptance sampling plans using large sample sizes. Small sample sizes are referred to 10 samples at Stage 1 and 30 samples at Stage 2, which are required in USP <905>. Large sample sizes are referred to at least hundreds of samples as in EU Option 1 and EU Option 2.

Acceptance Sampling Plans for Small Samples

USP <905> UDU Acceptance Sampling Plan

The USP <905> consists of a tolerance interval test and two indifference zones. Let $\bar{X}$ and s be respectively the sample mean and sample variability of a random sample. The 1st indifference zone is for samples with mean value $\bar{X} \leq 98.5\%$ and the 2nd indifference zone is for sample with mean value $\bar{X} \geq 101.5\%$. For the 1st indifference zone, 98.5% will be used instead of $\bar{X}$ for the tolerance limit calculation. For the 2nd indifference zone, 101.5% will be used instead of $\bar{X}$ for tolerance interval calculation. The USP <905> can be described as follow.

At the 1st Tier, collect a random sample of 10 tablets from the batch and assay these 10 tablets. Let $M = 98.5\%$ if $\bar{X} < 98.5\%$, $M = 101.5\%$ if $\bar{X} > 101.5\%$, and $M = \bar{X}$ otherwise. The batch compiles if $M - 15\% < \bar{X} - 2.4 \cdot s < \bar{X} + 2.4 \cdot s < M + 15\%$ and all 10 measurements are within 75–125% M . Otherwise go to the 2nd tier.

At the 2nd Tier, assay the remaining 20 tablets and use the total 30 measurements to update $\bar{X}$ and s . Let $M = 98.5\%$ if $\bar{X} < 98.5\%$, $M = 101.5\%$ if $\bar{X} > 101.5\%$, and $M = \bar{X}$ otherwise. The batch compiles if $M - 15\% < \bar{X} - 2.0 \cdot s < \bar{X} + 2.0 \cdot s < M + 15\%$ and all 30 measurements are within 75–125% M .

PTIT

The objective of a PTIT with 95% confidence and 87.5% coverage for UDU acceptance sampling test is to ensure with 95% confidence that the percentages of tablets below 85% and above 115% LC are both less than 6.25% of the batch. The PTIT acceptance sampling plan is proposed to ensure that the percentage of over-filled tablets and the percentage of under-filled tablets are both below a specific limit.^[4,11] The PTIT acceptance sampling plan consists of two one-sided tests. The first one-sided test is applied to ensure that the percentage of over-filled tablets is below 6.25%. The test is carried out by comparing the upper limit of a left one-sided 95% confidence bound and 93.75% coverage tolerance interval with 115%. Recall that $\bar{X}$ and s be respectively the sample mean and sample variability of a random sample. The one-sided 95% confidence level tolerance interval $(-\infty, \bar{X} + Ks)$ with 93.75% coverage probability is calculated by solving for K in the following

$$\text{equation: } \Pr \left\{ \int_{-\infty}^{\bar{X} + Ks} f(x : \mu, \sigma) dx \geq (1 + 87.5\%)/2 \right\} = 0.95,$$

where μ and σ are the population mean and the standard deviation of random variable X , respectively, and $f(x : \mu, \sigma) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(x-\mu)^2}{2\sigma^2}}$. K is often called the one-sided tolerance factor. Faulkenberry and Daley^[12] showed that $K\sqrt{n}$ is the 95% percentile of a noncentral t distribution with $n - 1$ degrees of freedom and a noncentrality parameter, $-Z_{93.75\%}\sqrt{n}$.

When $\bar{X} + Ks < 115\%$ LC, it ensures that the percentage of over-filled tablets is less than 6.25%. Similarly, when $\bar{X} + Ks > 85\%$ LC, it ensures that the percentage of under-filled tablets is below 6.25%.

The two-stage PTIT acceptance sampling plan can be described as follows. In the first tier, assay a random sample of 10 tablets from a batch and calculate $\bar{X}$ and s . Accept the batch if $85\% < \bar{X} - K_1s < \bar{X} + K_1s < 115\%$, where $K_1\sqrt{n} = t(n - 1, -\sqrt{n}Z_{(1+P)/2}, 1 - \alpha_1)$, where $t(n - 1, -\sqrt{n}Z_{(1+P)/2}, 1 - \alpha_1)$ is the $100 \cdot (1 - \alpha_1)^{\text{th}}$ percentile of a noncentral t distribution with $n - 1$ degrees of freedom and the noncentral parameter $-\sqrt{n}Z_{(1+P)/2}$, P is the coverage within (85, 115)% LC, e.g., $P = 0.875$. Note: α is the overall type 1 error rate; α_1 is the type 1 error rate for first tier when we control the nominal value α of 2-tier sequential test, e.g., at 0.05.^[13]

In the second tier, assay a random sample of an additional 20 tablets from the batch and use the total 30 measurements to update $\bar{X}$ and s . Accept the whole batch if $85\% < \bar{X} - K_2s < \bar{X} + K_2s < 115\%$, where $K_2\sqrt{n} = t(n - 1, -\sqrt{n}Z_{(1+P)/2}, 1 - \alpha_2)$, $100 \cdot (1 - \alpha_2)^{\text{th}}$ percentile of a noncentral t distribution with $n - 1$ degrees of freedom, and the noncentral parameter $-\sqrt{n}Z_{(1+P)/2}$. Note α_2 is the type 1 error rate for the second tier when we control the overall type 1 error rate of the two-tier sequential test as α , e.g., 0.05.

Acceptance Sampling Plans for Large Samples

Although there are several versions of the counting method^[5–9], we will focus on EU Option 2 in European Pharmacopoeia 8.1 since all counting methods share certain statistical properties as EU Option 2.

EU Option 1

EU Option 1 is based on two-sided tolerance interval modified with an indifference zone. For normally distributed variable, the two-sided tolerance interval with $1 - \alpha$ confidence level and P coverage is commonly represented in the form $(\bar{X} - K^*s, \bar{X} + K^*s)$. Here, K^* can be numerically calculated by solving the equation below.

$$\Pr \left\{ \int_{\bar{X} - K^*s}^{\bar{X} + K^*s} f(x : \mu, \sigma) dx \geq P \right\} = 1 - \alpha$$

The acceptance sampling test is implemented as follows:

With a sample of n (≥ 100) units, we calculate the acceptance value (AV) using the following formula:

$$|M - \bar{X}| + K^*s$$

Here, K^* is sample size-dependent tolerance factor and is defined in Table 2.9.47-1 of European pharmacopoeia 8.1; M is defined by the value of sample mean $\bar{X}$, such that $M = 98.5\%$ if $\bar{X} < 98.5\%$; $M = 101.5\%$ if $\bar{X} > 101.5\%$; and $M = \bar{X}$ otherwise.

The following criteria are applied, unless otherwise specified.

The requirements for dosage form uniformity are met if:

1. the acceptance value (AV) is less than or equal to $L1$ ($= 15.0$ unless other specified), and
2. in the calculation of acceptance value (AV) under content uniformity or under mass variation, the number of individual dosage units outside $(1 \pm L2 \times 0.01)M$, where $L2 = 25$ unless otherwise specified, is less than or equal to $c2$, as defined for a given sample size n in Table 2.9.47-1 of European pharmacopoeia 8.1.

EU Option 2

EU Option 2 is a nonparametric acceptance sampling test defined as follows:

With a sample of n (≥ 100) units, count the number of individual dosage units with a content outside $(1 \pm L1 \times 0.01)100$ LC and the number of individual dosage units with a content outside $(1 \pm L2 \times 0.01)100$ LC. Here $L1 = 15$ and $L2 = 25$. A batch passes the test for the uniformity of dosage units if

1. The number of individual dosage units outside $(1 \pm L1 \times 0.01)100$ LC is less than or equal to $c1$; and
2. The number of individual dosage units outside $(1 \pm L2 \times 0.01)100$ LC is less than or equal to $c2$.

Here, $c1$ and $c2$ are listed in Table 2.9.47-2 of European pharmacopoeia 8.1.

PTIT_matchUSP90

Again recall that $\bar{X}$ be the sample mean and s the sample standard deviation of contents of n units. Unlike USP <905> with a two-tier procedure, PTIT_matchUSP90 is a single tier content uniformity test with large sample size of n . A batch passes the PTIT_matchUSP90 test if $(\bar{X} - K(n)s, \bar{X} + K(n)s) \in (85\%, 115\%)LC$, where $K(n)$ is the tolerance factor for the PTIT_matchUSP90 sampling test using n units and is derived as follows.

The PTIT_matchUSP90 test consists of two one-sided hypothesis tests which ensure that the proportions of

over-filled and under-filled tablets are both under control. Let $p(n)^{[10]}$ be the desired proportion of the population within the interval (85%, 115%) LC for the PTIT_matchUSP90 sampling test using n units. In general, the acceptance probability of a batch with a given standard deviation when the mean is 100% LC increases with an increase of n for a fixed coverage within the interval (85%, 115%) LC. Since the PTIT_matchUSP90 test is designed to have 90% acceptance probability for any n at the standard deviation at which USP <905> has 90% acceptance probability when the batch mean is 100% LC, then we must increase $p(n)$ within the interval (85%, 115%) LC. The first one-sided test is to ensure that the proportion of over-filled tablets ($>115\%$ LC) is less than $(1 - p(n))/2$ and the second one-sided test is to ensure the proportion of under-filled tablets ($<85\%$ LC) is also less than $(1 - p(n))/2$. The first test is carried out by comparing the upper one-sided tolerance interval with 95% confidence level and $(1 + p(n))/2$ coverage with the upper limit 115% LC. More specifically, this one-sided tolerance interval is in the form of $(-\infty, \bar{X} + K(n)s)$, where the tolerance factor $K(n)^{[12]}$ is solved by the following equation for given values of μ and σ :

$$\Pr \left\{ \left[\int_{-\infty}^{\bar{X} + K(n)s} f(x; \mu, \sigma) dx \right] \geq \frac{1 + p(n)}{2} \right\} = 0.95$$

Where $f(x; \mu, \sigma) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(x-\mu)^2}{2\sigma^2}}$. It can be easily showed that for normally distributed random variable, $K(n) = t_{n-1, 1-\alpha} \left(Z_{(1+p(n))/2} \sqrt{n} \right) / \sqrt{n}$ where $Z_{(1+p(n))/2}$ is the 100 $(1 + p(n))/2\%$ -th percentile of the standard normal distribution and $t_v(\gamma)$ denotes the non-central t -distribution with degree of freedom v and non-centrality parameter γ . If $\bar{X} + K(n)s < 115\%$ LC, it ensures that the percentage of over-filled tablets is less than $(1 - p(n))/2$. Similarly, if $\bar{X} - K(n)s > 85\%$ LC, the second test ensures that the percentage of under-filled tablets ($<85\%$ LC) is less than $(1 - p(n))/2$.

The algorithm to obtain $K(n)$ and $p(n)$ is briefly described below under normality and the detail was referred.^[14] First, $K(n)$ is determined for any n such that the probability of the event of $(\bar{X} - K(n)s, \bar{X} + K(n)s) \in (85\%, 115\%)LC$ is 90% at the standard deviation at which USP <905> has 90% acceptance probability when the batch mean is 100% LC. Second, $p(n)$ is determined by satisfying the equation $K(n) = t_{n-1, 1-\alpha} \left(Z_{(1+p(n))/2} \sqrt{n} \right) / \sqrt{n}$. Once we have $K(n)$, the acceptance probability of a batch with an individual table content as a random variable can be obtained from Monte Carlo simulations.

DISCUSSIONS

In Section 3.1, we discuss bias of USP <905> based on the comparison of acceptance probabilities between the

USP <905> acceptance sampling plan and PTIT acceptance sampling plan for small samples. In Section 3.2, we discuss the difference between EU Option 1 and PTIT_matchUSP90 for large samples. In Section 3.3, we discuss the difference between EU Option 2 and PTIT_matchUSP90 for large samples.

USP <905> and PTIT for Small Samples

The USP <905> acceptance sampling plan has often been modified through the years based on the capability of manufacturing without proper statistical support. As a result, the USP <905> often turns out to be both biased and incapable of inferring the characteristics of the population (the batch). Shen and Tsong^[11] showed the USP harmonized plan is biased in favor of batches with off-target means because of its indifference zones. The bias of the procedure is displayed with the plots of the acceptance probability against the coverage percentage (inside 85%–115% LC range) of the batch (See Figures 1–8, Shen and Tsong^[11]). The USP <905> has much higher acceptance probability for batches with off-target means (i.e., the batch mean $\neq$ 100% LC) than batches with on-target means when the coverage percentage within the interval 85%–115% is the same. In contrast, the acceptance probability curves of the PTIT do not differ much for batches with different target means. Furthermore, the PTIT has a slightly lower acceptance probability for the batches with off-target means than batches with on-target means when the coverage within the 85%–115% interval is greater than 0.91.

Hence, Shen and Tsong^[11] recommend that USP remove the indifference zone and replace the current USP harmonized content uniformity test with PTIT.

EU Option 1 and PTIT-matchUSP90 for Large Samples

As shown earlier, the tolerance factor K is free of batch mean and standard deviation. We calculated k values using $K = t_{n-1, 1-\alpha} \left(\frac{Z_{1+p(n)}}{2} \sqrt{n} \right) / \sqrt{n}$, where $\alpha = 0.05$ and $p(n)$ is coverage for sample size n . EU calculated K for various sample sizes n by adopting $\gamma = 0.84$ and $\beta = 0.91$:

$$K = Z_{\frac{1-\beta}{2}} \sqrt{\frac{n-1/n}{\chi_{\gamma, n-1}^2}}, \text{ where } Z_{\frac{1-\beta}{2}} \text{ is the critical value of the}$$

normal distribution and $\chi_{\gamma, n-1}^2$ is the critical value of the chi-square distribution with $n-1$ degrees of freedom.

From Table 1, it can be seen that the K values for PTIT_matchUSP90 are smaller than those for EU option 1 for each corresponding sample size.^[10] Hence it is expected that the acceptance probability of PTIT_matchUSP90 should be always higher than that of EU option 1 for a given population if EU option 1 uses a tolerance interval as the only decision rule. In fact, this is not always true because EU option 1 is two-sided tolerance interval

Table 1 Comparison of K values between PTIT_matchUSP90 and EU Option 1

Sample Size	PTIT_matchUSP90	Option 1
100	2.0475	2.15
1000	2.2321	2.27

method modified with an indifference zone and counting outside of $(0.75M, 1.25M)$.

Differences in acceptance probabilities between EU Option 1 and PTIT-matchUSP90 can be summarized as follows.^[10]

First, there is a large difference in acceptance probability among EU option 1 and PTIT_matchUSP90 when the batch mean is off-target. More specifically, for a batch with off-target mean with data either of a single normal distribution or of a mixture of two normal distributions, EU option 1 has much higher acceptance probability than PTIT_matchUSP90. For instance, the OC curve of PTIT_matchUSP90 is left to that of EU option 1 with 102% LC at any given large sample size, e.g., 100 and 1000, respectively as shown in Figures 2, 7, and 8.^[10] As the sample size increases, the differences in the OC curve between PTIT_matchUSP90 and EU option 1 both become larger. Moreover the acceptance probability of PTIT_matchUSP90 is almost zero for a batch with standard deviation 6.6%; however, the acceptance probability is about 27% for EU option 1. In addition, the counting number outside $(75\%M, 125\%M)$ LC criterion in EU option 1 has little impact on the acceptance probability under normality assumption. For instance, adding counting test in EU option 1 only reduces the acceptance probability by 0.23% for $\mu = 102$, $\sigma = 6$, and $n = 100$.

Second, there is no apparent difference in acceptance probability among EU Option 1 and PTIT_matchUSP90 for a batch with on-target mean (100% LC). According to our simulation study, EU option 1 has a slightly lower acceptance probability than PTIT_matchUSP90 at a given sample size and standard deviation when data are either taken from normal distribution or from a mixture of two normal distributions.

Third, there is bias in EU option 1. The acceptance probability of EU option 1 at mean of 102% LC is much larger than that of PTIT_matchUSP90 at mean of 102% LC under normality assumption. This contradicts the observation that the acceptance probability of EU option 1 at mean of 100% LC is smaller than that of PTIT_matchUSP90 at mean of 100% LC under normality assumption because K value in EU 1 is a slight larger than K value in PTIT_matchUSP90 for sample size of 1000. This contradiction is most likely resulted from indifference zone in EU1.

Fourth, it is also clearly shown (see Figure 9)^[10] that the difference in OC curves of EU option 1 between batches with mean of 102% and of 100% LC is much smaller than the difference in OC curves of PTIT_matchUSP90 between batches with mean of 102% and of 100% LC. This means that the PTIT_matchUSP90 has more power in discriminating off-target batches from on-target batches.

As discussed in,^[11] the indifference zone criterion used in USP harmonization method induce bias that results in favoring batches with off-target mean. The undesirable behavior of EU option 1 is also observed in.^[10] Hence, we recommend that European Pharmacopoeia investigate the impact of indifference zone and consider removal of the indifference zone criterion from EU option 1 and replacement of EU option 1 with two one-sided parametric tolerance intervals.

EU Option 2 and PTIT-matchUSP90 for large samples

It is well understood that content values may not be normally distributed and a non-parametric content uniformity acceptance sampling plan may need to be developed. However, when developing a new large sample non-parametric approach, we need to provide assurance of proper power to satisfy small sample compendia method USP <905> applied to samples at any time. Any method should not fail the basic requirement that samples on shelf should pass USP <905> at any time. For a lack of publication of mathematical or statistical derivation of the approach, we can only evaluate the EU Option 2 in European pharmacopoeia 8.1 through simulation studies.^[15] PTIT_matchUSP90 is developed to assure 90% acceptance probability at the standard deviation where USP <905> has 90% acceptance probability for batches with 100% LC mean. The following are the summaries of such evaluations.^[15]

Under normality, the acceptance probability of EU option 2 is slightly higher than that of PTIT_matchUSP90 for batches with a large variability. However, under normality, EU Option 2 is not sensitive to the off target mean since the acceptance probability of EU Option 2 is much larger than that of PTIT_matchUSP90 for batches with large variances. Furthermore, EU Option 2 is not sensitive to large variances and a mean shift under a mixture of two normal variables as the PTIT_matchUSP90 is.

Given that 97% of tablets have content values falling within the range from 85% LC to 115% LC, clearly EU Option 2 is not sensitive to a large variability in contents from a uniform distribution; on other hand, EU Option 2 is over-sensitive to a small percent of extreme observations. As a result, EU Option 2 provides low assurance to be accepted by USP <905> in the subsequent compendia testing. The EU Option 2 is not sensitive to the mean shift of the majority population (97%) from 100% LC to 90%

LC. In addition, the EU Option 2 is not sensitive to low assay values (about 90% LC). Together, it shows that it may be hard to declare the EU Option 2 is a good sampling test in the sense of providing high probability assurance of acceptance by the subsequent USP<905> compendia test. Certainly, the examples simulated are extremes for any batch with consistent good quality. However, they are useful to illustrate the potential problems of interpreting a variable acceptance sampling test (e.g., tolerance interval method) with an acceptance sampling by attribute test (e.g., counting test).

In conclusion, the counting method such as EU Option 2 performs insensitively for a batch with a large variability and an off target mean even under normality and a mixture of two normal variables, and performs over-sensitively for a batch with small percent of low extreme values. For content uniformity assessment, information such as variability can be lost when EU Option 2 is used.

RECCOMENDATION

Parametric two one-sided tolerance interval test is recommended for batch release based on small samples. PTIT_matchUSP90 is recommended for batch release based on large samples.

Abstract

In this entry, we illustrate the three approaches in analysis of dose-ranging trials which include the multiple comparison procedure (MCP), the modelling (MOD) approach, and the combined MCP-Mod approach. We illustrated these procedures with implementation in R with a real clinical trial data set.

Keywords: Clinical trials; Dose-finding; Multiple comparison; Family-wise error-rate (FWER); Dose-response modeling; Emax model; MCP-Mod.

INTRODUCTION

Traditionally, proof of concept (PoC) study and dose-ranging trials are conducted separately in a sequential fashion. A two-group PoC design involves a comparison between MTD (Maximally Tolerable Dose) of test drug and a placebo control, a comparison that is conducted first. Only after the concept is proven, then dose-ranging trials are designed to study the dose-response relationship. In recent years, more sponsors are combining these two steps into one – using one trial with multiple doses to serve both the PoC and dose-ranging purposes. The focus of this entry is to discuss data analysis of dose-ranging trials – either this dose-ranging trial is designed after PoC or in combination with the PoC objective.

In the analysis of dose-ranging clinical trials, there are typically three approaches commonly used to help determining the dose-response relationship: the first is a multiple comparison procedure (MCP) approach, the second is to use a dose-response modeling (Mod) approach and the third to combine both the MCP and Mod as a newer approach, which is commonly referred as “MCP-Mod” approach (Bretz et al. 2005^[1]; Pinheiro et al. 2006^[2]).

In the MCP approach, the dose is treated as a qualitative factor with a set of dose levels from the dosages available for testing in the clinical trial. In this approach, there are usually no assumptions about the underlying dose-response relationship and the statistical inferences to find doses of interest are restricted to this set of studied doses. In contrast to the MCP approach, the “Mod” approach typically assumes a parametric dose-response

relationship between the dose and the efficacy response in the trial. Then the doses are treated as a quantitative continuous variable that would allow more flexibility for dose finding. Therefore, the validity of this “Mod” approach would depend strongly on the assumed dose-response model.

Combining both the MCP and Mod approaches, Bretz et al. (2005^[1]) developed an MCP-Mod approach to unify the MCP and Mod approaches, which is to assume the existence of several candidate parametric dose-response models and use multiple comparison techniques to choose the one most likely to represent the true underlying dose-response curve. At the same time, the hybrid MCP-Mod approach preserves the family-wise error rate. The selected model is then used to provide inference on adequate doses. Based on this novel approach, Bretz and colleagues developed an R package (i.e. “MCP-Mod”) which is publicly available at <http://cran.r-project.org/web/packages/MCPMod/index.html> with detailed description in Bornkamp et al. (2009^[3]). This package later became part of the new package in “DoseFinding” which can be freely accessed at <https://cran.r-project.org/web/packages/DoseFinding/index.html>.

This entry is then organized as following sections. Section 2 provides the data set and some preliminary analyses. Section 3 presents analysis for making a PoC decision. The multiple comparison procedures (MCP) are introduced in Section 4 and the modeling (Mod) approach in Section 5. In Section 6, we introduce the combined MCP and Mod approach (MCP-Mod) and conclude the entry with a discussion in Section 7.

DATA AND PRELIMINARY ANALYSIS

Let's first describe the data. As reported in Bretz et al. (2005^[1]), this study was a randomized double-blind parallel group trial with a total of 100 patients being allocated to either placebo or one of four active doses coded respectively as 0.05, 0.20, 0.60, and 1, with $n = 20$ per group. The response variable was assumed to be normally distributed with larger values for a better outcome. The data is publicly available in R packages "MCPMod" and "DoseFinding" as a data frame named "biom" with 2 columns named "dose" for dose levels and "resp" for responses. There are 20 observations for each of the 5 dosages. The data are available from both R packages. The data distributions at each dose can be graphically illustrated in Figure 1 with a boxplot and it can be seen from Figure 1 that the response distributions are overlapped indicating large variations existed in this data. Also as seen from Figure 1, there is an observed monotonic increasing dose-response relationship with sample means of 0.345, 0.457, 0.810, 0.934 and 0.949, respectively.

ESTABLISHING POC WITH A TREND TEST

The PoC can be established based on the contrast test for statistical significance. Let μ_i be the population mean for dose group i ($i = 0, 1, \dots, k$), where μ_0 is the mean from the placebo group. For example, k is 4 corresponding to the "biom" data in Section 2 and the estimated sample means of μ_i ($i = 0, 1, 2, 3, 4$) are 0.345, 0.457, 0.810, 0.934 and 0.949, respectively.

To construct a contrast for PoC, let c_i be the corresponding contrast coefficients with the condition that $\sum_{i=0}^k c_i = 0$.

Then the null hypothesis (H_0) of no treatment effect versus the one-sided alternative hypothesis (H_A) of significant treatment effect (PoC) can be written as follows:

Figure 1 Boxplot for Dose-Response Distribution for dataframe "biom"

$$H_0 : L(\mu) = \sum_{i=0}^k c_i \mu_i \leq 0 \text{ vs. } H_A : L(\mu) = \sum_{i=0}^k c_i \mu_i = \delta > 0 \quad (1)$$

If at the design stage, the planned PoC step is based on a trend test, then, corresponding to "biom" data with $k = 4$, the trend contrast coefficients are $c = (c_0, c_1, c_2, c_3, c_4) = (-2, -1, 0, 1, 2)$, which can be found in Table 2 in Wang and Ting (2012^[4]), and the above hypotheses become as follows:

$$H_0 : L(\mu) = (-2)\mu_0 + (-1)\mu_1 + 0\mu_2 + 1\mu_3 + 2\mu_4 \leq 0, \text{ vs.}$$

$$H_A : L(\mu) = (-2)\mu_0 + (-1)\mu_1 + 0\mu_2 + 1\mu_3 + 2\mu_4 = \delta > 0.$$

The test statistic can then be constructed as a one-sided t-test as follows:

$$T = \frac{\widehat{L(\mu)}}{SE(\widehat{L(\mu)})} = \frac{\sum_{i=0}^k c_i \bar{x}_i}{SE\left(\sum_{i=0}^k c_i \bar{x}_i\right)} \quad (2)$$

where $\bar{x}_i$ is the sample mean of μ_i and SE denotes its standard error.

We can fit an analysis of variance (ANOVA) model to estimate the sample means and their associated standard errors using R function "lm" (i.e., linear model) to fit the ANOVA model with summary table as shown below:

Estimate	Std. Error	t value	Pr(> t)	
dose=0	0.3449	0.1593	2.165	0.0329
dose=0.05	0.4568	0.1593	2.867	0.0051
dose=0.2	0.8103	0.1593	5.087	1.83e-06
dose=0.6	0.9344	0.1593	5.866	6.47e-08
dose=1	0.9487	0.1593	5.956	4.35e-08

Residual standard error: 0.7124 on 95 degrees of freedom
Multiple R-squared: 0.5336, Adjusted R-squared: 0.509
F-statistic: 21.74 on 5 and 95 DF, p-value: 1.897e-14

We can see that the ANOVA model is statistically significant with p-value = 1.897e-14 and a $R^2 = 53.36\%$. The estimated means are labeled under the column "Estimate" for all the doses which are all statistically significant as shown for their associated p-values. The estimated standard deviation, also known as the residual standard error, is 0.7124. We can extract these values for PoC calculations.

Under the same study setting, the design could have pre-specified a PoC just like the traditional high dose against placebo comparison –

$$H_0 : L(\mu) = -\mu_0 + \mu_4 \leq 0, \text{ vs.}$$

$$H_0 : L(\mu) = -\mu_0 + \mu_4 > 0.$$

In this case, the t -test as given in (2) can still be applicable, where the contrast coefficients are now $-1, 0, 0, 0, 1$. The study result indicates a p -value of 0.00867, indicating the null hypothesis is rejected and the concept is considered proven.

The statistical test for PoC in equation (2) can then be easily calculated with these estimates and shown to be true. This established the PoC for these data and the next step is to identify the dose from the dose range where the statistically significant difference occurs with MCP, Mod, and MCP-Mod approaches.

MULTIPLE COMPARISON PROCEDURE (MCP) APPROACH

By nature of design, dose-response trials typically include multiple dose groups plus a control. Therefore a multiple comparison procedure should be utilized to adjust for multiplicity. For example, in this data, there are four doses of 0.05, 0.2, 0.6, 1 plus the placebo dose. There are many procedures in multiple comparison adjustment and we illustrate the most commonly used procedures, such as the Fisher's protected least significant difference (LSD), Bonferroni procedure, Dunnett's procedure, Holm's procedure, Hochberg, and gate-keeping procedures.

Fisher's Protected LSD (Fixed Sequence Test)

As a comparison, we first illustrate the naïve MCP procedure which was termed as Fisher's protected LSD (least significant difference). This procedure is also known as the "fixed sequence test" in Westfall and Krishen (2001^[5]) and in Bretz et al. (2005^[1]) to determine the dose using a 5% one-sided level. The first step is to perform an F -test to see if there is any difference among all treatment groups. Only after this test is significant, then to perform pairwise comparisons of each dose against placebo. This can be easily conducted using the R function " lm " for all pairwise comparison to placebo as summarized as follows:

	Estimate	Std. Error	t value	Pr(> t)
(Intercept)	0.3449	0.1593	2.165	0.03287
Dose=0.05	0.1118	0.2253	0.497	0.62068
Dose=0.2	0.4654	0.2253	2.066	0.04155
Dose=0.6	0.5895	0.2253	2.617	0.01032
Dose=1	0.6038	0.2253	2.680	0.00867

Residual standard error: 0.7124 on 95 degrees of freedom

Multiple R-squared: 0.1153, Adjusted R-squared: 0.07808
F-statistic: 3.096 on 4 and 95 DF,
p-value: 0.01921

It can be seen that the overall model fitting is statistically significant with two-sided p -value = 0.019 from the F -test statistic of 3.096 with degrees of freedom of 4 and 95. The values in the column "Estimate" corresponding to "dose" 0.05, 0.2, 0.6 and 1 are the estimated mean difference to the placebo dose, that is, $\mu_i - \mu_0$, which are 0.1118, 0.4654, 0.5895 and 0.6038, respectively. Examining the corresponding p -values at the column "Pr(>|t|)", we can see that they are all statistically significant as two-sided t -test except the dose at 0.05. As a default setting in R function " lm ," the column "Pr(>|t|)" reported the 2-sided p -values which can be converted a one-sided p -value. The one-sided raw p -values (i.e. raw.pval) can then be calculated as follows:

Dose=0.05	dose=0.2	dose=0.6	dose=1
0.310339936	0.020774426	0.005160541	0.004334960

This reproduced the results at their Table 2 (page 743) from Bretz et al. (2005^[1]). Therefore, this fixed sequence test concluded that the top three doses (i.e. 0.2, 0.6 and 1) were statistically significantly different to placebo.

Bonferroni Correction

As a way to adjust for multiple comparisons, the classical Bonferroni correction (Bonferroni 1935^[6] 1936^[7]) adjusts the raw p -values, ensuring strong family-wise error-rate (FWER) control under arbitrary dependence of the raw p -values. It simply multiplies each raw p -value by the total number of hypotheses. We make use of the R package of "mutoss" which is maintained by the MUTOSS (multiple hypotheses testing in an open software system) team and can be downloaded from <http://mutoss.r-forge.r-project.org/>. This package is designed to unify the application and comparison of multiple testing procedure. Most of the MCP procedures are implemented in this package and we only need to call the corresponding function. The Bonferroni correction procedure can be done by calling the R function Bonferroni to the raw p -value where the "raw.pval" is the vector of unadjusted p -values for the pairwise comparison (i.e., $\mu_i - \mu_0$) which is from the ANOVA model fitting above. The output of this Bonferroni correction with the adjusted p -values and rejected at $\alpha = 0.05$ can be shown as follows:

dose=0.05	dose=0.2	dose=0.6	dose=1
adjPValues:			
1.00000000	0.08309770	0.02064217	0.01733984
Rejected:			
FALSE	FALSE	TRUE	TRUE

From this output, we can find the adjusted p -values associated with each comparison of the specific dose to placebo. With alpha (α) = 0.05, it also showed whether the comparison was rejected or not. Among the four pairwise multiple comparisons, the doses of 0.05 and 0.2 were not rejected, whereas the top two doses of 0.6 and 1 were rejected.

Dunnett's Test

Dunnett's test is also to compare each of the dose treatments to the placebo treatment. This test was developed in Dunnett^[8] and updated in Dunnett^[9]. The procedure takes advantage of positive correlations among pairwise comparisons. The fact that each dose is compared with the same placebo control makes all pairwise comparisons to be positively correlated. Dunnett's test was widely used in multiple comparison procedure for simultaneously comparing, by interval estimation or hypothesis testing, all active dose treatments with placebo when the outcome is sampled from a distribution where the normality assumption is reasonable. This test is designed to hold the familywise error rate at or below α when performing multiple comparisons of treatment group with control. To implement the Dunnett's test, we make use of the R package "DoseFinding". The "MCTtest" function in this package gave the Dunnett's contrast to compare all the dose treatments to the placebo and the test-statistic with the adjusted p -values for each dose treatment as follows:

Multiple Contrast Test		
	t-Stat	adj-p
Dose=1	2.680	0.0153
Dose=0.6	2.617	0.0178
Dose=0.2	2.066	0.0653
Dose=0.05	0.497	0.6033

It can be seen from the multiple contrast test that the doses of 0.05 and 0.2 were not statistically significant and the other top two doses of 0.6 and 1 were statistically significant (adjusted p -value less than the nominal alpha of 0.05).

Holm's Step-down Procedure

The Holm's step-down-procedure was developed in Holm^[10] and detailed in Huang and Hsu^[11]. The terms "step-down" or "step-up" are in reference to the absolute values of t -test. "Step-down" implies the procedure starts with the pairwise t -test with the largest absolute value, and then steps down to the smaller absolute value of t . It controls the family-wise error rate (FWER) and offers a simple test uniformly more powerful than the Bonferroni correction. The Holm's procedure is implemented in the R package "mutoss" with function "holm." The function

"holm" is called to adjust the raw p -values "raw.pval" to control FWER and the output is produced as follows:

dose=0.05	dose=0.2	dose=0.6	dose=1
adjPValues:			
0.31033994	0.04154885	0.01733984	0.01733984
Rejected:			
FALSE	TRUE	TRUE	TRUE

The Holm's test showed that the dose of 0.05 was not rejected. However, the doses of 0.2, 0.6 and 1 were rejected as each of them is statistically significantly different from placebo.

Hochberg Step-up Procedure

The Hochberg procedure (Hochberg^[12]) is based on marginal p -values. It controls the FWER in the strong sense under joint null distributions of the test statistics that satisfy Simes' inequality as summarized in Sarkar and Chang^[13]. Huang and Hsu^[11] compared this Hochberg procedure with Holm's procedure in Section 9.4.4 and concluded that the Hochberg procedure is more powerful than Holm's^[10] procedure, but the test statistics need to be independent or have a distribution with multivariate total positivity of order two or a scale mixture thereof for its validity. Whereas Holm's procedure is a step-down version of the Bonferroni test, Hochberg's is a step-up version of the Bonferroni test. Note that Holm's method is based on the Bonferroni inequality and is valid regardless of the joint distribution of the test statistics.

The Hochberg procedure is implemented in R function "hochberg" in R package "mutoss" which produces following output:

dose=0.05	dose=0.2	dose=0.6	dose=1
adjPValues:			
0.31033994	0.04154885	0.01548162	0.01548162
criticalValues:			
0.01250000	0.01666667	0.02500000	0.05000000
Rejected:			
FALSE	TRUE	TRUE	TRUE

With the same conclusion reached as the Holm's procedure, the Hochberg's procedure showed that the dose of 0.05 was not rejected and the doses of 0.2, 0.6 and 1 were rejected and hence statistically significantly different from placebo.

Gate-keeping Procedure

Gate-keeping procedures are proposed to test hierarchically ordered hypotheses from clinical trials. The hypotheses are grouped into ranked families, such that the hypotheses in higher order ranked families are tested first and the lower ranked families can be tested only if rejections achieved for higher ranked families. In other words,

the higher ranked families serve as gatekeepers for lower ranked ones.

In general, there are two types of gatekeeping procedures known as serial and parallel gate-keeping procedure. As discussed in Bauer et al.^[14] and Dmitrienko et al.^[15], the serial gatekeeping requires all hypotheses in one family be rejected before testing the next family, whereas parallel gatekeeping as discussed in Dmitrienko et al.^[16] only requires at least one hypothesis be significant in order to test the next one. The gatekeeping approaches were first proposed as closed tests as discussed in Marcus, Peritz and Gabriel^[17] by considering all possible configurations of the null hypotheses where in general, the number of computational steps grows exponentially with n (about 2^n calculations need to be performed to test n null hypotheses). Under the assumption of the nondecreasing dose response with respect to increasing doses, the multiple testing of individual doses could fit into the serial gate-keeping procedure by ordering the testing sequence from the highest to the lowest dose. A lower dose is tested only if all preceding higher doses are tested and rejected at level of significance (α , α). The testing stops once a hypothesis fails to be rejected.

This gate-keeping procedure can be easily implemented to start with the highest dose and then goes down to find the minimal dosage where dosage to placebo is statistically significant at this dosage, all higher doses should be significant which can be seen as follows:

Dose=0.05	dose=0.2	dose=0.6	dose=1
FALSE	TRUE	TRUE	TRUE

Same as the Holm's and Hochberg's procedures, the gate-keeping procedure showed that the dose of 0.05 was not rejected and the doses of 0.2, 0.6 and 1 were rejected, with each being statistically significantly different from placebo at the 0.05 level of significance.

MODELING APPROACH (MOD)

Different from the MCP approach discussed in the Section 4, the modeling approach (Mod) treats dose as a continuous variable and assumes a functional relationship between the response and the dose. Sometimes, the multiplicity issue is avoided as a result of the assumed functional relationship (e.g., non-decreasing dose–response relationship).

Dose-response Models

The dose-response models are used to describe certain functional relationship between the observed responses y_{ij} and the corresponding dose d_i , where i indicates the dose-level from 1 to k ($k = 5$ in the “biom” data) and j indicates the observations in each dose level from 1 to n_i ($n_i = 20$ in the “biom” data for all 5 dosages). This model can be mathematically expressed as follows:

$$y_{ij} = f(d_i, \theta) + \varepsilon_{ij}.$$

where ε_{ij} is the error term. The mean response $\mu_i = E(y_{ij})$ and the corresponding dose d_i can then be expressed as

$$\mu_i = f(d_i, \theta).$$

where $f(\cdot)$ is a linear or nonlinear function of dose d and the vector of modeling parameters θ . There are potentially many types of dose-response models, such as the linear model, linear in log-dose model, the exponential model, the quadratic model, the logistic model, the Emax model, the sigmoid Emax model and the beta model. These models are briefly summarized in Table 1 with their functional form and the associated model parameters.

Table 1 Commonly Used Dose-Response Models

Model	Functional form	Parameters
Linear	$E_0 + \delta d$	E_0, δ
Linear in log-dose (linlog)	$E_0 + \delta \log(d)$	E_0, δ
Exponential	$E_0 \exp(d/\delta)$	E_0, δ
Quadratic	$E_0 + \beta_1 d + \beta_2 d^2$	E_0, β_1, β_2
Logistic	$E_0 + \frac{E_{max}}{1 + \exp((ED_{50} - d)/\delta)}$	E_0, E_{max}, δ
Emax	$E_0 + \frac{E_{max} d}{ED_{50} + d}$	E_0, E_{max}, ED_{50}
Sigmoid Emax	$E_0 + \frac{E_{max} d^\lambda}{ED_{50}^\lambda + d^\lambda}$	$E_0, E_{max}, ED_{50}, \lambda$

The graphical presentation of these models can be shown in Figure 2.

In this presentation, we specified these models with some selected parameters and also we illustrated two Emax models and two logistic models. As seen from Figure 2, all these models except for the quadratic model are monotonic increasing as doses increase.

Among these models, a very popular dose-response model is the sigmoid Emax model as seen in Table 1. This sigmoid Emax model is a four-parameter model where E_0 is the effect at dose 0 (the placebo response); E_{max} is the maximum effect attributable to the drug; ED_{50} is the dose, which produces half of E_{max} ; and λ is the slope factor (Hill factor). In practice, the three-parameter Emax model is typically considered, assuming the Hill factor $\lambda = 1$. As discussed in Thomas^[18], the Emax model can fit very well for most of the actual dose-response data and we illustrate this Emax model in this entry for the Mod approach.

R Implementations

We fit the Emax dose-response model to the “biom” data using the R function “fitMod” as in follow R code: fitMod(dose, resp, data = biom, model = “emax”). With the

Emax model, the model fitting can be graphically illustrated in Figure 3. It can be seen from Figure 3 that the Emax model fitted the “biom” data very satisfactorily. In Figure 3, the dashed vertical lines at each observed dosage indicated the confidence intervals for the means at those observed dosages. The solid curve in the middle is the fitted Emax model, which is closed to the observed mean responses at each observed dosages. The confidence interval for the fitted Emax model can be seen from the upper and lower curved lines about the fitted Emax model.

It is important to note that the modelling approach is, by nature, an estimation process and hence p-values are not directly interpretable. In order to help readers who are used to p-values, these numbers are still presented below. We calculate the t-statistics and the associated p-values at dose-levels of 0.05, 0.2, 0.6 and 1 are:

Dose=0.05	dose=0.2	dose=0.6	dose=1
0.1216920183	0.0207664633	0.0007128031	0.0003555304

It can be seen that treatment effects start from dose 0.20 and indicates that the top three doses of 0.2, 0.6 and 1 are can be considered as different from placebo.

Figure 2 Shapes of dose-response models in Table 2

Figure 3 Model fitting to “biom” using Emax model where the curves as Upper 95% CI, Predicted, Lower 95% (from top to bottom)

MCP-MOD APPROACH

As the third approach in analyzing dose-response trials, the MCP-Mod method is to combine the MCP approach in Section 4 and Mod approach in Section 5 into one unified approach by first selecting the dose-response model using MCP to protect the FWER; then, the selected model is used to estimate the dose-response relationship (readers are encouraged to refer to the MCP-Mod entry of this Encyclopedia). This approach is flexible in the sense of model selection; on the other hand, it pays the price of splitting α at the model selection step.

This MCP-Mod approach was developed by Bretz et al.^[1] and they further developed an R package (i.e. “MCPMod”) (Bornkamp et al.^[3]) which is available at <http://cran.r-project.org/web/packages/MCPMod/index.html>. We do not intend to replicate the theory in this entry but instead concentrate on illustration of this package for real data analysis. We again make use of the “biom” data for this illustration. This illustration is largely described in Bornkamp et al.^[3] and this entry is a further application of this package.

Implementations in R package “MCPMod”

The first step to use MCPMod is to select a candidate set of models for approximating the underlying dose-response

relationship. The package gave a list of candidate models to be used, such as linear model, log-linear model, quadratic model, logistic model, exponential model, beta-model, Emax model, and sigmoid Emax model. In addition to these models, the users can also define their own non-linear models. The candidate models should be specified as a list with the list elements named according to the underlying dose-response model function, along with guesstimates or NULL for the model parameters. For illustration purpose, let’s specify the candidate model lists for the “biom” dose-response data as follows:

```
# Specify the candidate model list
> modlist = list(linear=NULL,
  linlog=NULL,
  betaMod = c(0.5, 1), logistic=c(0.25,
    0.09),
  quadratic=-1, exponential=1,
  emax=c(0.05,0.2), sigEmax=c(0.1,1))
```

We deliberately select the candidate model list, which is different from the models used in Bretz et al.^[1], to show flexibility of the MCPMod to perform in model fitting and model selection. Bretz et al.^[1] used linear model, log-linear model, two exponential models, two quadratic models and the Emax model, whereas we select the linear model,

log-linear model, beta model, logistic model, quadratic model, exponential model, Emax model and sigmoid Emax model, respectively, as seen in the above R code chunk.

We named the selected model list as an R object “modlist” and the numerical values are the guestimated parameter initial values. It can be seen that this candidate model list includes some monotonic increasing functions (such as the linear model, log-linear model, logistic model, exponential model, Emax model and sigmoid Emax model) as well as other shapes of models (such as beta model and quadratic model).

The main function in this package is also named as “MCPMod.” It provides all the functionalities of the full MCP-Mod approach and includes two key steps:

1. MCP-step to calculate the optimal contrasts, critical value, contrast test statistics and possibly p -values, and selection of the set of significant models,
2. Modeling step for model fitting, model selection/model averaging, and dose estimation.

We call this function to analyze the “biom” and the following simple R code chunk is all that is needed for MCP-Mod analysis:

```
# Fit the MCP-Mod
>fit.MCPMod = MCPMod(biom, modlist,
  alpha = 0.05, pVal = TRUE,
  selModel = "maxT", doseEst = "MED2",
  clinRel = 0.4, dePar = 0.05)
# Print the summary of model fitting
>summary(fit.MCPMod)
```

We now explain some of the most important arguments used for the MCPMod function. It can be seen from the above R code chunk that the first argument is the dose-response data set (i.e., biom in this case) followed by the candidate model list (i.e., modlist defined previously). The alpha is the level of significance for the multiple contrast test, specified as $\alpha = 0.05$. The pVal argument is to determine whether multiplicity adjusted p -value for the multiple contrast test should be calculated or not and we specified it as $pVal = TRUE$. The selModel argument is a dose-estimation criterion to determine how to select a dose-estimation model from the set of significant models (if there are any significant models). The argument doseEst is to determine the minimum effective dose (MinED) once the overall dose-response relationship is established from an adequate model fitting. The MinED is defined as the smallest dose that demonstrates a clinically relevant and a statistically significant effect (denoted by Δ), specified as “clinRel.” Four dose-estimation options can be selected. One option is called “ED” to estimate the dose that gives a pre-specified percentage of the maximum effect. Specifically, the target dose ED_p is defined as the smallest dose that gives a certain percentage p of the maximum effect

Δ observed in the dose range of $(d_1, d_k]$. The other three options are defined in Bretz et al. (2005) as “MED1,” “MED2” and “MED3” with default selection of “MED2.” The dePar argument is used to specify additional parameters for the four dose estimators. For ED-type estimators, it determines which effective dose is estimated with the default 0.5 to estimate ED50. For MED-type estimators, it determines the confidence level γ used in the estimator. The used confidence level is given by $1 - 2\gamma$ in corresponding to $1 - 2\gamma$. In the R code chunk, we specified doseEst = “MED2” with dePar = 0.05 and clinRel = 0.4 to use the MED2 estimator with $\gamma = 0.05$ and the clinical threshold $\Delta = 0.4$ to estimate the MED. This configuration means that we wish to determine the smallest dose such that the lower limit of the 95% confidence interval for the predicted response is greater than the predicted response for placebo and the point estimate is 0.4 above the predicted placebo level.

With all those settings, the summary of the MCPMod model fitting is given by print(fit.MCPMod) as follows:

Input parameters:

```
alpha = 0.05 (one-sided)
model selection: maxT
clinical relevance = 0.4
dose estimator: MED2 (gamma = 0.05)
```

Multiple Contrast Test:

	Tvalue	pValue
emax2	3.464	0.001
sigEmax	3.462	0.001
linlog	3.364	0.002
emax1	3.339	0.003
logistic	3.235	0.003
linear	2.972	0.007
exponential	2.752	0.012
betaMod	2.402	0.030
quadratic	1.850	0.093

Critical value: 2.156

Selected for dose estimation:

emax

Parameter estimates:

```
emax model:
  e0  eMax  ed50
0.322 0.746 0.142
```

Dose estimate

```
MED2,90%
0.17
```

where:

1. Input parameters for some information about important input parameters that were used for MCPMod modelling.
2. “Multiple Contrast Test” and “Critical value” are the contrast test statistics, the

multiplicity adjusted p -values from the multivariate t -distribution in Bretz et al.^[1], and the critical value associated with the candidate models specified in the modlist. It should be noted in this part that all contrast tests with an adjusted p -value less than 0.05 or equivalently with t -value > 2.18 (the critical value) can be declared as statistically significant, with FWER maintained at 5% level. Of these nine candidate models only the quadratic model is not statistically significant, which is then not used in the reference set.

3. “Selected for dose estimation” and “Parameter estimates” for the best fitted dose-response model from the candidate models and its parameter estimates. For these data, the best model is found to be the “Emax” model with estimated parameters as $E_0 = 0.322$, $E_{\max} = 0.746$ and $ED_{50} = 0.142$.
4. “Dose estimate” for the target dose estimate from this MCP-Mod modeling, which is 0.17 based on the settings in this modeling and close to the estimate from MoD approach at Section 4.

In summary for the MCP-Mod approach, the best model selected for dose estimation from the model list is the Emax model and the estimated significant dosage is 0.17.

DISCUSSION

In this entry, we used a real data set “biom” to illustrate the three approaches in analysis of dose-ranging trials, namely, the MCP approach, the Mod approach, and the combined MCP-Mod approach. We illustrated these procedures with implementation in R and the R program can be obtained from the authors upon request.

With the established PoC using a trend test (or the two group comparison) in Section 3, we introduced six MCP procedures in Section 4 to control the FWER to identify the dosage which are statistically significantly different from placebo. These six approaches are the Fisher’s protected LSD (fixed sequence test), the Bonferroni test, the Dunnett test, the Holm’s test, the Hochberg test, and gate-keeping test. Among the six MCP tests, the Bonferroni test and the Dunnett test identified that the top two doses (i.e., 0.6 and 1) were statistically significantly different from placebo and the rest of four tests (i.e., the fixed sequence test, the Holm’s test, the Hochberg test and gatekeeping test) identified the top three doses (i.e., 0.2, 0.6 and 1) were statistically significantly different from placebo.

The Mod approach in Section 5 used the Emax model to estimate the dose-response relationships. With the estimated dose-response Emax model, we further illustrated the estimation of doses of interest along with their confidence intervals. We also investigated other models, such as

the log-linear and the sigmoid Emax model (as an extension of Emax model to include another parameter) and found that both models gave the same conclusions (not shown here due to the space limitations).

The combined MCP-Mod approach in Section 6 selected the best model as the Emax model from a list of dose-response models that included the linear model, log-linear model, logistic model, exponential model, Emax model, the sigmoid Emax model, the beta model, and the quadratic model. With the best model being Emax, the statistically significant dose was identified as 0.17.

Dose Proportionality

C. Gordon Law

Pfizer Inc., Groton, Connecticut, U.S.A.

Abstract

In drug development, it is essential to manage a safe and effective dosing. This entry gives a brief overview of statistical models for assessing dose proportionality.

INTRODUCTION

In drug development, it is essential to manage a safe and effective dosing. While a complete pharmacokinetic (PK) profile for all doses is impossible to establish, prediction of PK effects in a certain dose range can easily be made if the compound possesses the property of dose proportionality (DP). This property, also called dose independence or linear pharmacokinetics, implies that rates of absorption, distribution, metabolism, and elimination remain constant over the dose range. With this property, plasma concentration, area under the plasma concentration–time curve (AUC), maximum plasma concentration ($C_{\max}$), and urinary recovery should increase in direct proportion to dose.

OVERVIEW

Fig. 1 depicts a typical pattern of a PK profile with DP. It is assumed that dose 1 < dose 2 < dose 3. The left panel of the figure shows that the concentration–time curve shifts upward as the dose increases. The shapes of the three concentration curves at the absorption and the excretion stages are nearly identical. As shown in the middle panel, if the concentrations are divided by the corresponding doses, the difference will be indistinguishable. In the right panel, the three AUC values almost fall on the same line when they are plotted against dose. Similarly, a linear relationship for $C_{\max}$ can be observed.

In case of repeated dosing, the concentration after multiple dosing can be well projected if the pharmacokinetics of the drug are time invariant and are dose independent. Based upon the superposition principle,^[1] the concentrations over time can be predicted by laying the profile of the next dose over the residual concentrations resulting from all previous doses. Rowland and Tozer^[1] describe the circumstances when DP cannot be established.

For the statistical methods to assess DP, Ezzet and Spiegelhalter^[2] and Hutchison and Keene^[3] provide excellent reviews. They proposed a power model to estimate

the degree of proportionality. Besides this approach, two popular models—linear regression and analysis of variance (ANOVA)—are also used to assess DP. All of these models will be reviewed and compared in the following section. Some limitations in these models will be examined. In the last section, the design aspects of the DP study will be discussed. Some interesting works by Ezzet and Spiegelhalter^[2] will be illustrated.

STATISTICAL MODELS FOR ASSESSING DOSE PROPORTIONALITY

Linear Regression

The classical approach to test DP is to fit a few regression models using the key PK parameters, denoted by Y , as the response and the dose level as the covariate. Because heterogeneity in variances is often found in DP studies, the models are usually fitted with weights equal to the reciprocal of the dose level or with a transformation for Y . The model for initial assessment can be:

$$Y = a + b(\text{dose}) + c(\text{dose})^2$$

When the coefficient for the quadratic term c is not significantly different from zero, dose linearity is claimed. The next model of interest is:

$$Y = a + b(\text{dose})$$

If the intercept a is not significant, then DP can be declared. In other words, it requires dose linearity and zero intercept to assess DP.

The main drawback of the regression approach is the lack of a measure that can quantify DP. If the measure existed, we could have derived a confidence interval describing the uncertainty of the estimate. Also, when the quadratic term is significant or when the intercept is not close to zero, we are unable to estimate the magnitude of departure from DP.

Fig. 1 Pharmacokinetic profile under dose proportionality

Besides the classical approach, Haynes and Weiss^[4] proposed the following biphasic model to assess DP:

$$Y = \begin{cases} b_1 \text{ dose} & 0 < \text{dose} < x_0 \\ b_2 \text{ dose} & x_0 < \text{dose} < x_{\max} \end{cases} \quad \text{if}$$

They modeled DP as a change-point problem and considered the slope ratio b_2/b_1 to be a measure of DP. When the slope ratio is greater than 1, it may reflect capacity-limited elimination or first-pass effects or both. If the ratio is less than 1, it may reflect increased clearance or reduced absorption or both.

Analysis of Variance

The second popular approach to analyze DP studies is to use ANOVA. Before analysis, correction to the response is made by dividing the response by dose. If the response is proportional to dose, such adjustment will make the corrected response constant. Each dose level is assumed to be associated with a treatment effect. Thus the basic model can be written as:

$$\frac{Y_j}{(\text{dose})_j} = \mu + \alpha_j$$

where j is the index for dose level, μ denotes the grand effect, and α denotes the treatment effect. If the hypothesis $H_0: \alpha_1 = \alpha_2 = \dots = 0$ is not rejected with an overall F -test, then DP is claimed. Otherwise, statistical methods for multiple comparison can be employed to test if any individual's α_j s are close to zero or to assess the differences among dose levels. Yuh et al.^[5] proposed a step-down method using Helmert contrasts to assess DP.

Unlike the regression procedure, the basic model of this approach does not need to assume any relationship among doses. However, because it ignores the ordering of doses, the approach is not as efficient as the regression. Given the estimates of the model, it is difficult to predict the response for the doses not actually studied.

Power Model

According to an empirical relationship between AUC of $C_{\max}$ and dose, Troy et al.^[6] used the following power model to assess DP:

$$Y = a(\text{dose})^\beta$$

In this model, the exponent of dose, β , is a measure of DP. When $\beta = 0$, it implies that the response Y is independent of dose. When $\beta = 1$, DP is declared. The effect of changing dose can be evaluated by:

$$\frac{Y_{j'}}{Y_j} = \left(\frac{(\text{dose})_{j'}}{(\text{dose})_j} \right)^\beta$$

Thus when the dose is doubled, the response is expected to increase by a factor of 2^β .

It should be noted that, after log transformation, the model will become linear:

$$\log Y = \alpha + \beta \log(\text{dose}) \quad \text{where } \alpha = \log a$$

The usual linear regression procedures can then be applied in this situation. Because the log transformation tends to stabilize the variance, we do not need to select any weights to correct the heterogeneity in variance. In fact, following FDA guidelines,^[7] the assumption on the normal error term can be well justified under the transformation.

The primary objective of a DP study is to examine the relationship between the key PK parameters and dose. Rather than test DP solely, it is desirable to estimate the degree of DP or the effects of dose change and to describe the uncertainty. For obtaining confidence intervals, the analysis of the raw ratio in the linear regression model relies on the use of Fieller's method, whereas it is straightforward in the power model. Also, the confidence intervals based on the power model are relatively narrower than with the ANOVA model because dose order and values are ignored in the latter.

DESIGN OF THE DOSE-PROPORTIONALITY STUDY

Recall that the DP study purports to compare doses and to estimate their effects on the key PK parameters. It should not be conducted with any designs where background factors may confound with dose. Usually, Latin squares or a balanced incomplete block design is considered. However, when these crossover designs are used, it is necessary to justify additional sources of variation in models. For example, if the power model is used to fit the PK data, we may consider the following model:

$$\log Y_{ijk} = \alpha_i + \beta \log(\text{dose}_j) + P_k$$

where α_i is the i th subject effect and P_k is the k th period effect.

Dose selection is often dictated by safety concerns, which involve the results of other PK studies. From a statistical perspective, the optimal design for estimating β (or b in linear regression) is to select the lowest and highest doses with equal observations. However, it is unwise to assess DP with only two doses because the relationship between the PK parameters and the dose can be quadratic or in other nonlinear patterns. In practice, at least three doses should be used in a DP study.

When more than three doses are available, one can make the dose selection by comparing the design matrix of

our model. To illustrate the idea, Ezzet and Spiegelhalter^[2] considered the following model

$$\log \text{AUC}_{ij} = \alpha_i + \beta \log(\text{dose}_j) + \gamma [\log(\text{dose}_j)]^2$$

They specified five doses—25, 50, 100, 200, and 400 mg—and assumed a maximum of five doses per subject. Using the criterion of minimizing the standard error of model estimates, they compared the diagonal element in $(\mathbf{X}'\mathbf{X})^{-1}$ corresponding to β and γ , where $\mathbf{X}$ is the design matrix. For a three-period crossover study, the optimal dose combination was found to be (25, 100, 400). Similar comparisons were also made for crossover design with four and five periods.

Dose Response Analysis in Clinical Trials

James MacDougall

Genzyme, Cambridge, Massachusetts, U.S.A.

Abstract

Dose response analysis plays an integral role in the process of finding an optimal dose or range of doses for physicians to prescribe. This entry explores the factors that influence dose response analysis and discusses different trial designs for testing these factors.

INTRODUCTION

A primary objective of clinical trials in the drug development process is the selection of an optimal dose or range of doses for physicians to prescribe. Dose–response analysis plays an integral role in achieving this objective. Ruberg^[1] summarizes the objectives of dose–response analysis into the following four questions.

1. Is there any drug effect?
2. What doses exhibit a response different from control?
3. What is the nature of the dose–response relationship?
4. What is the optimal dose?

The design and analysis of a dose–response study should be in accordance with the objectives of the study. The choice of study design for a dose–response study depends on the therapeutic area, phase of drug development, and the endpoint(s) of interest. Ruberg,^[2] Ting,^[3] and Sheiner^[4] review the clinical trial design aspects of dose–response studies.

REGULATORY GUIDELINES

The ICH E-4 guideline “Dose–Response Information to Support Drug Registration”^[5] provides broad guidelines on the design and analysis of dose–response studies. The ICH E-9 guideline “Statistical Principles for Clinical Trials”^[6] also briefly discusses trials to show dose–response relationships. The following is a summary of the guidelines relative to dose–response analysis.

- Assessment of the dose response should be an integral part of establishing the safety and efficacy of the drug.
- When available, dose concentration data are useful and should be incorporated into the dose–response analysis.

- Dose–response information should be derived from well-controlled studies based on accepted statistical methodologies. In addition to the formal dose–response analysis, the entire database should be examined for dose–response information.
- A parallel dose–response study design provides group mean (population average) dose response, not individual dose–response information.
- A titration design can have difficulties from a dose–response analysis standpoint, with the potential of overestimating the optimal dose.
- A forced titration design has the disadvantage of not being able to distinguish between a response to increased dose from a response to increased time on drug.
- Crossover designs have potential drawbacks, but have the advantage that each individual receives several different doses.
- Regulatory agencies and sponsors should be open to new approaches and receptive to reasoned exploratory data analysis in analyzing and describing dose–response data.
- A well-controlled dose–response study is also a study that can serve as primary evidence of effectiveness.
- Depending on the objective, the use of confidence intervals and graphical methods may be as important as the use of statistical tests.

CHARACTERIZING THE DOSE RESPONSE

In general, a dose–response curve can be characterized by its minimum effect, maximum tolerability, variability of response at a particular dose, rate of change in response as the dose changes, and potency. Determining the minimum effective dose is an important part of an efficacy trial. Finding the maximum tolerable dose (the highest dose with an acceptable safety profile) is critical for safety considerations.

Tests for Determining Drug Effect

An initial objective of dose–response analysis is determining if there is any drug effect. Hamaski,^[7] Tamhame,^[8] and Phillips^[9] review various methods of testing for a drug effect. The following are brief nontechnical descriptions of common methods for detecting a drug effect.

Linear Trend

A widespread and straightforward approach to dose–response analysis is to apply regression methods to determine if there is a linear dose response.^[10] The dose or concentration is a covariate and regression methods are used to determine if there exists a linear trend.

Overall *F*-Test

In the analysis of variance (ANOVA) setting, test the null hypothesis that all the means are equal. Variations of this method include testing only the highest dose vs. placebo and pooling all active doses and testing vs. placebo.^[11,9]

Contrasts

In the ANOVA setting, linear contrasts can provide powerful methods for detecting dose response. Stewart and Ruberg^[11] and Ruberg^[1] review methods of creating linear contrast tests powered for estimated dose–response alternatives.

William's Test

Based on a monotonic dose–response alternative, the estimate of the highest group mean is compared to the control group.^[12,13] William's testing methodology can also be used in estimating the minimally effective dose MED.

Bartholomew's Test

This is a modification of the *F*-test based on applying a monotonic order restriction to the likelihood ratio principle.^[14–16]

Jonckheere's Test

This is a rank-based method utilizing an ordered alternative comparing the number of times an observation from a higher-dose group is larger than an observation from the lower-dose group.^[17]

Cochran–Armitage Test

This method is used for detecting a linear trend across dose groups in proportions of events when the outcome is binomial.^[18,19]

Although no one test can be universally recommended for all scenarios, the results of Phillips^[9] indicate that tests incorporating the ordering of the dose groups are powerful against a variety of dose–response patterns and should be considered when the objective is to determine if there is a dose response. Further information on order-restricted inference is given in Barlow et al.^[20]

Minimally Effective Dose and Maximum Tolerated Dose

A common objective in characterizing the dose response of a compound is determining the MED. Ruberg,^[1] Källén and Larsson,^[21] and Senn^[10] review the concept of MED and methods of determining the MED. A key issue surrounding the MED is that there is no universally accepted definition for MED. Ruberg^[1] proposed the following definition: “The minimally effective dose is the smallest dose producing a clinically important response that can be declared statistically, significantly different from the placebo response,” incorporating both clinical and statistical aspects MED.

The maximum tolerated dose (MTD) is an important concept in dose–response clinical trials as it defines an upper limit in determining an optimal dose. Similar to the MED, there is no universally accepted definition of MTD for clinical trials. Culter et al.^[22] discuss various issues surrounding the MTD.

Sigmoid Models

It is often reasonable to assume that the dose–response relationship will be sigmoidal in nature. In pharmacokinetics/pharmacodynamics, the E_{MAX} model is commonly used to characterize the dose–response curve.^[21,23,24] This model is represented by the following equation: $R = E_0 + (D^N \times E_{MAX}) / (D^N + ED_{50}^N)$. Where R is the response, E_0 is the Baseline Effect, D is the dose, E_{MAX} is the maximum drug effect, ED_{50} is the dose at half-maximal effect, and N is the slope factor (often called the Hill factor). The E_{MAX} model can estimate useful parameters in determining an optimal dose; for example, the ED_{90} , the dose that yields 90% of the maximum effect could be used as an estimate for the optimal dose. This model is most appropriate when there is sufficient number of different doses (or concentration range) such that the dose response can be accurately characterized. This model can also be extended to a mixed model when subjects are assessed at more than one dose level.

Mixed-Effects Models

If the design of the trial is such that different doses are measured within the same subject, it may be beneficial to utilize mixed-effects modeling to characterize the dose–response curve. This method has the advantage

that it is based on dose response at the subject level and not the population. Mixed-effects modeling for dose–response analysis can be either linear or nonlinear. Information on mixed-effects models with applications to dose–response analysis can be either linear or nonlinear. Information on mixed-effects models with applications to dose–response analysis and clinical trials is given in Zhang and Gould,^[25] Källen and Larsson,^[21] and Davidian and Giltinan.^[26]

Orthogonal Polynomials

Orthogonal polynomials can be used to characterize the shape of the dose response by determining if there are polynomial trends in the dose response.

Nonparametric Regression

As mentioned in regulatory guidelines, the appropriate use of graphical methods may be as important as statistical tests. Nonparametric regression can be a useful tool in dose–response visualization and informally assessing goodness of fit for a parametric dose–response model. Nonparametric regression estimates a smooth function based on the data. Two popular methods are kernel regression and smoothing splines. More detailed information on nonparametric regression is given in Hazelton^[27] and Hardle.^[28]

DETERMINING WHICH DOSES ARE EFFECTIVE

In the later-phase clinical trials, the objective of the study is to determine which doses demonstrate a response different than control. Testing multiple doses vs. control inherently raises the issue of multiplicity. It is anticipated by regulatory agencies that adjustment for multiplicity in a confirmatory clinical trial will be addressed and documented.^[6] One method of addressing the multiplicity issue is to control the overall familywise error rate of the hypotheses at a predefined level α by use of a multiple comparison procedure (MCP).

Descriptions of the theory and applications of MCPs can be found in Hochberg and Tamhane,^[29] Hsu,^[30] and Miller.^[31] A review of various MCPs applied to the clinical trial setting can be found in Tamhane and Dunnett,^[32] Zhang et al.,^[33] Lakshminarayanan,^[34] and Westfall et al.^[35] The following are brief nontechnical descriptions of common MCPs applied in dose–response analyses.

Bonferroni Adjustment

The standard Bonferroni adjustment tests each of k hypotheses at level α/k to control the familywise error rate at α .

Fisher's Least Significant Difference

Fisher's least significant difference test is a two-step method for controlling the familywise error rate in the ANOVA setting. The first step is an overall test of equality of treatment means at level α . If that test is rejected, the second step tests the individual hypotheses each at level α .

Bonferroni–Holm Procedure

Holm^[36] developed a uniformly more powerful sequential version of the single-step Bonferroni procedure based on ordering the p values. This procedure is referred to as a step-down sequential method as the p values are tested from smallest to largest.

Hochberg Sequential Procedure

Hochberg^[37] developed a sequential method of testing starting with the least significant p value. This procedure is referred to as a step-up sequential method as the p values are tested from largest to smallest. Any hypothesis rejected by the Bonferroni–Holm procedure will also be rejected by the Hochberg procedure. The Hochberg sequential procedure does not guarantee control of the familywise error rate for all types of dependence among p values. However, simulation studies have shown that the method is conservative for most scenarios that would arise in a dose–response setting.^[38]

Dunnett's Procedure

Dunnett^[39] developed a single-step MCP for testing multiple treatments against a control incorporating the normality of the observations and the correlation structure. This method can be extended to both step-down and step-up sequential MCP tests.^[40]

Fixed Sequential Testing Procedure

Fixed sequential testing predefines the sequence of the hypothesis tests. The first hypothesis is tested at level α . If the first hypothesis is rejected, test the second hypothesis at level α . If the second hypothesis is rejected, test the third at level α and so on.^[1,35,41] In contrast to other sequential methods, the hypothesis testing order is defined a priori, not determined by the magnitude of the corresponding p values. This method has also been referred to as the “step-down” method because in studies comparing multiple doses to a control in a monotonic dose setting, the a priori ordering would generally be from highest dose to lowest.

In general, if your primary interest is in hypothesis testing, sequential MCPs provide better power than their single-step counterparts. The choice of which particular MCP to utilize depends on the endpoint, the hypotheses

being tested, the underlying assumptions of the MCP, and the alternatives you wish to be powered for.

ANALYSIS CONSIDERATIONS BASED ON TRIAL DESIGN

Three common dose–response trial designs are the parallel, crossover, and dose-escalation (titration) designs. The following table taken from Sheiner^[4] contrasts various design and analysis aspects of the three different dose–response designs.

The following is a brief summary of study design specific issues in dose–response analysis.

Parallel Group Designs

Randomized parallel-group dose–response studies are widely used in clinical trials. They have the advantage of being relatively straightforward in design and analysis. A disadvantage of the parallel-group design is that as a subject receives only one level of the treatment, the characterization of the dose response is at the population level not the individual level.

<i>Problem</i>	<i>Parallel dose</i>	<i>Crossover</i>	<i>Dose escalation</i>
Ethical	++	++	0
Problems in study execution			
Number of patients	<i>N</i>	<i>N/m</i>	<i>N/m</i>
Time	1 unit	<i>m</i> units	<i>m</i> units
Need for many centers	++	+	+
Complexity of protocol	0	+	+/++
Problems in study analysis			
Complexity	0	+	+
Reliance on modeling assumptions	0	+	++
Carryover effects	0	++	+
Period effects	0	++	+
Center effects	++	+	+
Few doses examined	++	++	0
Biased parameter estimates	+++	0	+
Poor/no estimates of variability	+++	+	+
Problems in extrapolation			
Not representative of individual response	+++	0	0
Not representative of clinical practice	++	+++	0
Not representative of patient group	+	+++	0

m = number of escalations/crossovers; 0 = problem absent; + = minor problem; ++ = moderate problem; +++ = major problem.

Crossover Designs

Senn^[42] reviews the design, analysis, and issues pertaining to crossover design clinical trials. Crossover designs have the advantage of a subject being assessed at multiple dose levels, allowing for the characterization of subject level dose response. Disadvantages of crossover designs are concerns surrounding carryover effects and treatment withdrawals.^[5,43] The analysis of crossover designs dose–response data should incorporate the repeated-measures aspect of the design.^[4] Further information on the analysis of crossover designs can be found in Senn^[42] and Rashid.^[44]

Titration Designs

Titration designs (or dose-escalation designs) are described in Refs.^[3–5,45] Titration designs have the advantage that they can be used to study a wide range of doses, the subject is assessed at multiple dose levels, and the design can provide clear evidence of dose effect.^[5] Disadvantages of this design are the potential confounding between dose and duration of treatment and concerns surrounding overestimation of the optimal dose.^[4–5,45–46] Further information on the analysis of titration designs can be found in Agin and Pun,^[45] Pun,^[47] Chuang,^[48] and Chuang-Stein and Shih.^[49]

ORDINAL ENDPOINTS

Most of the focus on dose–response analysis methods assumes that the endpoint is either continuous or binary. Chuang-Stein and Agresti^[50] review tests for detecting a dose–response relationship with ordinal response data.

SAFETY ENDPOINTS

Many of the dose–response analysis methods can be used for safety as well as efficacy endpoints. The following references focus on dose response for safety endpoints: Cutler et al.,^[22] Thall and Russell,^[51] O'Neill,^[52] and Hsu and Laddu.^[53]

COMBINATION-TREATMENT STUDIES

In some studies, the objective is to investigate dose–response relationships over a combination of therapies. In this type of study, special consideration must be given to compound hypotheses and multiple comparisons. Raghuvaran and Altan^[54] and Chow and Liu^[55] review response surface methodology. Further details on the analysis of combination-treatment studies are given in Hafner et al.,^[56] Phillips et al.,^[57] Hung,^[58] and Tangen.^[59]

CONCLUSION

Dose–response analysis is a fundamental part of the drug development process both in the early and later phases of clinical trials. Dose–response analysis determines if a drug effect exists, characterizes the dose–response curve, provides necessary information for choosing doses for future studies, and demonstrates safety and efficacy at a particular dose.

Because of the variety of objectives, designs, and endpoints that arise in the clinical trial setting, many dose–response analysis methods exist. There is no one dose–response analysis method that can be universally recommended. The choice as to which methods are most appropriate to apply should be based on the objectives and design of the trial.

Dose Response Study Design

Naitee Ting

Pfizer Global Research and Development, New London, Connecticut, U.S.A.

Abstract

Choosing the best designs for dose-response studies will help reduce the risk of recommending an incorrect dose for a new drug. The purpose of this entry is to review the considerations necessary to a successfully designed dose response study.

INTRODUCTION

For every drug that is available at the pharmacy, there is information regarding how much drug should be used by a patient. In many over-the-counter drugs, such information may also be available for adults and children separately.

From a physician's point of view, patients may respond to a drug differently according to age, gender, race, metabolism, or other characteristics. Hence, in practice, a physician may first prescribe a drug with a given dose based on the patient's background, and then the physician may adjust dosage depending on the patient's response to the prescribed drug.

All dosing information is based on the dose-response relationship obtained from the drug. Understanding the dose-response relationship is one of the most challenging tasks in drug development.

OVERVIEW

Conceptually, the efficacy of a drug increases as the dose increases (Fig. 1). The left curve plotted in Fig. 1 can be viewed as an efficacy-response curve; that is, the response (y-axis) represents some measure of the drug efficacy. In addition to efficacy response, there are also toxicity dose-response curves. We will assume, as shown in Fig. 1, when dose increases, both efficacy and toxicity increase. Based on these curves, the maximum effective dose (MaxED) and the maximum tolerable dose (MTD) can be defined: MaxED is the dose above which there is no clinically significant increase in pharmacological effect or efficacy, and MTD is the maximal dose acceptably tolerated by a particular patient population. Another dose parameter of interest is the minimum effective dose (MinED). Ruberg^[1] defines the MinED as "the lowest dose producing a clinically important response that can be declared statistically, significantly different from the placebo response."

In certain drugs, the efficacy curve and the toxicity curve are widely separated. When this is the case, there is

a wide range of doses for patients to take; that is, as long as a patient receives a dose between MaxED and MTD, the patient can benefit from the efficacy and at the same time avoid toxicities from the drug. However, for other drugs, the two curves may be very close to each other. Under this situation, physicians have to dose patients very carefully so that while benefiting the efficacy, patients do not have to be exposed to potential toxicity from the drug. The area between the efficacy and the toxicity curve is known as the "therapeutic window." One way to measure therapeutic window is to use the "therapeutic index (TI)." TI is defined as the ratio of MTD/MaxED. Clearly, a drug with a wide therapeutic window (or a high TI) tends to be preferred by both physicians and patients. If a drug has a narrow therapeutic window, then the drug will need to be developed carefully, and physicians will prescribe the drug with caution.

Oftentimes, drugs developed for life-threatening diseases (e.g., cancer or AIDS) tend to have narrow therapeutic windows. On the other hand, drugs developed to treat chronic diseases (e.g., high blood pressure, depression, high cholesterol, or arthritis) are required to have wide therapeutic windows because these drugs are frequently used in older patients, or patients with other concurrent diseases, and sometimes used in children.

The next section introduces the process of selecting doses in developing a new drug. The "General Design Considerations" section discusses some general considerations in designing dose-response clinical trials. "Drug/Disease Specific Considerations" presents a few special conditions, and the "Discussion" section covers the overall strategy in dose selection.

DOSE-SELECTION PROCESS FOR A NEW DRUG

In the drug development process, a new drug candidate would have to be studied in the laboratories first before it could be tested in humans. Drug testing that is performed in humans is called clinical trial, and tests out of humans

Fig. 1 Dose–response curves for efficacy and toxicity

are called nonclinical studies. Nonclinical studies are performed to evaluate various properties of the new drug. The knowledge obtained from these studies would then be used to help design and conduct clinical trials.

In nonclinical studies, pharmacokinetic (PK) and pharmacodynamic (PD) properties (details of PK and PD can be found in Vol. 1 of *Encyclopedia of Biopharmaceutical Statistics*) are studied to help identify dose–response relationships for the new drug. These data are useful in understanding how frequent and how much drug should be used to dose animals. Another important area of the nonclinical studies is toxicology. Drug toxicity is studied in a number of experiments. Results of these studies will help identify the toxic doses and types of toxicity to be anticipated in clinical trials. This information is useful in estimating the highest dose to be tested in humans.

There are four phases (phase I, II, III, and IV) in clinical development. The purposes of Phase I clinical trials usually include testing the PK properties and studying the safety of the test drug. These studies are mostly performed on normal volunteers. Sometimes surrogate markers are used in Phase I trials to study PD properties of the test drug. At the early stage of clinical testing, single-dose, dose-escalation designs are often used to study tolerability of the new drug. In a single dose, dose-escalation design, a few subjects are randomized to placebo and low dose of the test drug. If there are no adverse events, then another group of subjects is randomized to placebo and the next higher dose of test drug. This process is continued until either some adverse events are observed or until the top designed dose is reached. The information collected from these studies can be used to estimate the MTD.

In general, phase II clinical trials are designed to study the dose–response relationship. Usually, this is the first time the study drug is tested in patients with the disease under study. A typical phase II dose–response design randomizes patients into a few treatment groups, which include placebo and some low or high doses of the test drug. Fig. 2 shows the graph of a set of data simulated from a dose–response study with placebo and three active doses.

Sometimes it may take several phase II studies before a set of doses can be recommended for phase III clinical development. When in phase III, we usually assume that

Fig. 2 Observations from a simulated dose–response study

the doses are known. Phase III clinical trials are designed to confirm these findings. However, in some cases, results from phase III studies may still lead to dose changes. During or after the phase III program, a sponsor would put together a new drug application (NDA), which includes results and conclusions made from all of the nonclinical and clinical studies. The NDA is then submitted to regulatory agencies (e.g., Food and Drug Administration [FDA] in the United States) for review and approval. One important component of an NDA is the drug label. Dosing information should be well specified in the label. The dosing information is mainly obtained from phase II and phase III clinical trials.

After a new drug is approved, phase IV clinical studies are conducted. Some of these studies are referred to as “post-marketing surveillance” trials. One important purpose of these trials is to monitor the drug safety in the general patient population (as opposed to clinical trial patient population). Occasionally in postmarketing studies, we may see a drug is efficacious at a lower dose than the dosage recommended in drug label. This lower dose tends to provide a better safety profile. When this is the case, the drug label could be changed to include the lower dose as one of the recommended doses.

Based on the dose-selection process described above, it is obvious that selecting the right dose for a new drug is a very important process. Without dose information, it is not possible for a physician to prescribe the drug to patients. One of the regulatory documents that describes the importance and practical difficulties in the study of the dose–response relationship is International Conference on Harmonization (ICH) E4^[2] Guidance. Readers are encouraged to refer to this document for some of the regulatory viewpoints.

GENERAL DESIGN CONSIDERATIONS

Fig. 2 presents an example of data collected from a typical dose–response study design, which is sometimes referred to as a “randomized, double-blind, placebo-controlled, fixed-dose, parallel dose–response design.” In such a study, patients are randomized into a few predetermined dose groups (often include the placebo, a low dose, a medium dose, and a high dose), and they take the randomized dose for a period of time (usually several weeks to several months). After the study is

completed, the efficacy and safety data obtained from these patients are analyzed to study the dose–response relationship. Note that “parallel,” “fixed-dose,” and “placebo-control” are some important features of this design.

A parallel design is in contrast with a crossover design. In a 2×2 crossover design, a subject is randomized into one of two sequences. For one sequence, the subject takes treatment A for a period of time, and then takes treatment B after washout of treatment A. The treatment order is reversed for the other sequence. Sometimes more complicated crossover designs are utilized. In a parallel design, the subject is randomized to receive a treatment and stays on the same treatment until the end of study.

A fixed-dose design is in contrast with a dose-titration design. In a fixed-dose design, once a patient is randomized to a dose group, the patient would take the same dose of study drug throughout the complete dosing period. In a dose-titration design, a patient is randomized to a dose regimen with a starting dose, then the dose for a patient can be changed over time depending on the design, or on the patient’s response to the dose.

Fixed-Dose Vs. Dose-Titration Designs

In an escalating dose-titration study, subjects are randomized to start with a low dose, and depending on either patient’s response to the drug or a predetermined schedule, the dose is gradually increased until a suitable dose level is found. Each subject can receive more than one dose. A patient who responds to a low dose may stay on this low dose, and a patient who does not respond to a low dose after a fixed treatment period may receive the next highest dose of the drug. This procedure is repeated until some designed criteria are satisfied.

There are some advantages of a titration design. For example, a study with this design will allow a patient to be treated at the optimum dose for the patient; this dose-allocation feature reflects the actual medical practice. However, the disadvantage of a titration design is the difficulty in data analysis. For example, if a patient responded to the test drug after doses are escalated, it is unclear whether the higher dose or the accumulation of the lower dose causes the response. In titration designs with multiple treatment groups, there may be overlapping doses; for example, one treatment group is 10 mg escalating to 20 mg, and another group is 20 mg escalating to 40 mg. When this is the case, it is difficult to make inferences about the 20-mg-dose group.

In some cases, instead of a dose–response study, a concentration–response study is designed. A concentration–response study assesses efficacy and safety measurements observed from subjects according to the plasma concentration of the study drug, but not the doses of the study drug. There are many practical concerns in using this type of designs, e.g., how to blind the patient and the physician, how and when to measure the blood concentration, etc.

Because of the issues with dose-escalation designs and concentration–response designs, the parallel, fixed-dose designs are, in general, the preferred design for dose–response studies. Therefore, in most of the dose–response studies, patients are randomized to a few fixed-dose groups and are compared to a control treatment.

Selection of Control

Two types of controls can be considered in dose-finding designs: placebo control or active control. In some situations, an active control group may be used in dose–response study designs. The advantages and disadvantages of using an active control group depend on the disease under study, characteristics of the drug candidate being developed, and specific clinical inferences of interest (ICH E10).^[3] Studies with an active control, but without a placebo group, suffer from the additional burden of demonstrating that the treatment groups are effective, either through superiority to the active control or on the basis of some type of historical control information.^[4,5] An active control, however, may provide a reference against a treatment of “known” effectiveness.

In the early stage of clinical development of a new drug, it is a common practice (if deemed ethical) to compare the test drug with a placebo. This is important because detecting positive signals of effectiveness beyond that achieved with placebo is an important milestone for the continuing development of this drug. Accordingly, placebo plays an important role in a dose–response study—it represents a zero dose in the study. Patient response at zero dose is a basic standard for comparison with active doses. In typical dose–response studies, a few fixed doses (usually two, three, or four) would be chosen. These doses plus placebo make up the treatment groups for a randomized, dose–response trial.

Number of Doses to be Tested

Because there are difficulties in finding the right doses for a new drug, it is desirable to study as many doses as we can. However, the number of doses that can be tested in a given study is limited. There are practical constraints in determining the number of treatment groups. Most trials with sufficient number of patients are multicenter trials. Different centers may have different recruitment rates. As a result, there is an imbalance in the number of patients recruited by these centers. If this happens, some centers may fail to provide enough patients to be randomized to each treatment group, and the treatment by center interaction becomes nonestimable. Therefore, we have to limit the number of treatment groups in order to minimize the imbalance problem.

Another practical issue is dosage form. Sometimes there are only limited dosage forms available in the early stage of clinical development. When this is the case, the number

of doses to be used in a study may also be restricted. For some studies, the technique to achieve blinding is to produce matching placebos for each treatment group. The more doses that are included in a study, the more “matching placebos” may be needed. The number of dose groups may also be limited by practical considerations of how many pills we might reasonably expect a subject to take for any given dose. For these reasons and others, clinical studies designed with more than six or seven treatment groups are rare.

Sample Size Considerations

The general issue regarding sample sizes can be found in Vol.1 of *Encyclopedia of Biopharmaceutical Statistics*. When designing a dose–response study, the main concern in sample size calculation is how to handle multiple group comparisons. This issue is dictated by the objective of the study. A few examples of the objective of a dose–response study may be:

- Testing to see if a specific dose of test drug is different from placebo.
- Finding the minimum effective dose.
- Differentiating activities between active doses.
- Checking to see if there is an increasing trend.
- Demonstrating noninferiority between a particular dose and the active control.

As a good clinical practice, it is important to keep a single and clear primary objective for a single study. Hence, the above examples are mutually exclusive. For each of the objective in a given trial, the appropriate statistical method should be used to perform data analysis. Sample-size estimation should be consistent with the method used for data analysis.

In the first example, if the trial is designed to differentiate a specific dose of test drug from placebo, then the sample-sizing method would be similar to performing a two-sample *t*-test comparing the test drug against placebo. In most situations when analyzing dose–response studies, multiple comparison adjustments will be needed. Depending on the type of multiple comparison to be used for data analysis, sample sizes should be estimated accordingly. For example, if a stepwise multiple comparison adjustment will be used for analysis, then again, the two-sample *t*-test method is appropriate. On the other hand, if the Bonferroni adjustment is proposed for data analysis, then the same adjustment will have to be used in the sample-size-estimation procedure.

Dose Allocation, Dose Spacing

Dose–response studies are usually carried out in phase II. At this point, there is often considerable uncertainty regarding any hypothetical dose–response curve. It is typical at this time that the MTD is known from phase I studies, and it may

also be assumed that efficacy is nondecreasing with increasing dose. Even so, the underlying dose–response curve can still take many possible shapes. Given these assumed curves, there are various strategies of allocating doses. For example, if a drug is very potent and the efficacy curve rises rapidly at low dose, then we need to allocate doses at the low end to capture the drug activity. On the other hand, if the new drug is less potent and it takes some high doses in order to reach the desired efficacy response, then we need to choose a few high doses in the design. We can see that the dose-allocation strategy can be very different depending on the underlying dose–response curve.

After the number of dose groups is chosen, it is still a challenge to determine the high dose, low dose, and spacing between test doses. Typically, the high dose is a dose selected around or below the MTD, but choices of lower doses are often challenging. Wong and Lachenbruch^[6] introduce cases using equal dose spacing from low to high doses, i.e., divide the distance from placebo to highest dose by the number of active doses, then use that divided distance as the space between two consecutive doses (e.g., 20, 40, 60 mg). Others may consider some type of log dose spacing; e.g., 1, 2, 4, 8 mg for the design.

Optimal Designs

The dose levels and the number of subjects at each level can be chosen mathematically (using mathematical theory, simulation, or some other tools) in order to optimize a statistical criterion such as small errors of estimation. This set of dose levels and number of subjects at each level is called the statistically optimal experimental design, and the design depends on the chosen criterion and the underlying model for the dose–response curve.

The statistical principles of optimal experimental design can be applied to many of the study designs, and optimal design techniques can be used with various statistical models. Optimization techniques allow one to determine the statistically best set of doses and number of subjects to be used at each dose in order to estimate the parameters of the model, e.g., slope and ED50 (the dose that achieves 50% of efficacy response) in logistic regression, intercept and slope in linear regression. The doses used might not necessarily be those intended for use in the label, but they provide a basis for estimation of the dose–response curve so that the response at any dose can be predicted with good accuracy and precision. Depending on the optimality criterion chosen, the doses studied may not necessarily be equally spaced or have equal numbers of subjects at each dose. Information on the shape of the dose–response curve should be attained where possible from PK–PD studies and early phase II studies. This can then help the design of the late phase II study using the above principles.

A statistical approach to optimal experimental design is given in Pukelsheim.^[7] Wong and Lachenbruch^[6] review dose–response designs and use optimal design criteria for

linear and quadratic regression. They also use simulation to illustrate the effect of optimal design criteria on spacing of doses and the numbers of subjects at each dose.

DRUG/DISEASE SPECIFIC CONSIDERATIONS

The preceding section provides a general overview of considerations about dose–response study design. However, in some cases, there are special concerns; for example, for some diseases, it is not ethical to use placebo control. In this case, we need special designs to study drug efficacy. We present a few specific situations in this section, and discuss some of the concerns under these situations.

Drugs with Narrow Therapeutic Window

As indicated earlier, one characteristic of a good drug is that it is associated with a wide therapeutic window, i.e., the drug shows good efficacy at low doses, and it is safe even when doses are very high. Unfortunately, most drugs under development are associated with only a reasonable therapeutic window, and some drugs are with a very narrow therapeutic window. Doses for those drugs would have to be selected very carefully. In some cases, the appropriate doses may have to be determined according to individual patient characteristics. Titration designs and concentration–response designs may be reasonable approaches to deal with this issue.

Life-Threatening Diseases

In the development of drugs to treat certain life-threatening diseases (such as cancer or AIDS), the dose-selection process can be very different from what was described in the section “General Design Considerations.” Take cancer as an example. If a patient is diagnosed with cancer, the most important task is to help the patient survive. When survival is the top priority, patients tend to tolerate more drug toxicity, and a drug with narrow therapeutic window may be acceptable for these patients.

Cancer treatments include surgical operations, radiation therapy, and chemotherapy. Cancer drugs are often developed as a type of chemotherapy. Chemotherapy is usually dosed according to a patient’s body size, and is injected into the patient. Under this circumstance, it is difficult to conduct blinded studies. Hence, most chemotherapy clinical trials are not blinded. Another problem with cancer is that the use of placebo control is not ethical. Therefore, cancer trials typically include active agents, either as a control, or as background therapies. Generally speaking, chemotherapy is toxic, and because of high toxicity, it is not ethical to recruit normal volunteers for Phase I trials. Thus, in most of these drugs, cancer patients, instead of normal volunteers, are recruited for Phase I trials.

Drugs Developed for Prevention

Some drugs are developed for prevention purposes. One example is the use of female hormone supplement to prevent bone loss. In this case, the true clinical variable (clinical endpoint) of interest is bone fracture, which is very difficult to measure. If we design a study to observe bone fracture, we would need to follow many patients for many years. Hence, we use surrogate markers (e.g., bone mineral density) as the clinical endpoint in study designs.

However, the major challenge in developing drugs for prevention is that we can only propose very few doses, often with a single dose, on the drug label. The reason is that when a physician prescribes a drug for a patient to control his/her disease, the physician makes a dose adjustment according to the patient’s response to the prescribed dosage. If a drug is used for prevention, then it takes a very long time before any symptoms can be observed, and it is almost impossible for the physician to adjust the dosage. Hence, for this type of drug, the best recommendation is a single dose for prevention. The challenge in drug development becomes how to find this single dose for the drug label.

Drugs Need New Formulation

Some drugs are developed with TID (3 times a day) dosing or QID (4 times a day) dosing. In many cases, this dosing schedule can be inconvenient for patients, especially older patients. It is desirable to develop some type of slow-release formulation for these drugs so that a once-daily dosing is available. Doses used in the new formulation can be different from doses used in TID or QID dosing. Oftentimes a new formulation is developed as a new drug, and the dose-selection process will have to be repeated for the new formulation.

Drugs for Special Patient Population

Some drugs are developed for patients with chronic diseases. The population with chronic diseases generally includes older patients. Older patients tend to suffer from multiple diseases. Some of them may have liver or renal problems, in addition to the disease the drug is developed for. Doses used for this population need to be different from doses used for patients without these additional problems. In the development of these drugs, one problem is that not many such patients satisfy trial inclusion criteria, and hence there are only limited data in the entire clinical trial database. In most cases, dosing information for these patients is not available.

In the development of drugs for infectious diseases, one special population of interest is children. Doses used for children should be lower than doses used for adults. Hence, dose–response relationship established from phase II program for adults is not appropriate for pediatric use. Separate development programs are necessary to establish pediatric doses.

DISCUSSION

Dose selection in new drug development is a constant learning process. From nonclinical studies, we learn some preliminary dose information to help design early phase clinical trials. From phase I, we try to establish some PK information and to estimate the MTD. These data are used to design phase II studies. The key dose–response knowledge should be established during phase II. In phase III, we confirm these early findings. In the early stages, estimation is more important than hypothesis testing. We estimate the dose frequency, the efficacy dose–response curve, the toxic doses, and other parameters. In later phases, we use hypothesis testing to confirm these results.

In the phase II dose-selection process, it usually takes several dose–response studies before a final set of doses can be recommended for phase III. In order to speed up this process, some authors suggested sequential designs (Sitter and Wu^[8]) or adaptive designs (Palmer and Rosenberger^[9]) for dose selection. Hence, in an early phase II program, it is very important to choose the best design for dose response. Because dose selection is a critical task in drug development, we should consider planning for several dose–response studies at the beginning of phase II. The first study should cover a wide dose range in a hope that this study will help identify the doses where most of the activities are. The next study will then be designed to capture the dose–response relationship using information obtained from the first study. At early phase II, sequential designs or adaptive designs may not be able to provide the most reliable information to estimate the dose–response relationship.

CONCLUSION

Dose–response studies are critical because if we choose the wrong dose(s), the consequences are very expensive.

If wrong doses are brought into Phase III, all the Phase III studies designed to confirm these incorrect doses are wasted, and the development time line is severely delayed. If a drug is approved with a wrong dose in the label, there would be millions of patients taking the drug at a suboptimal dose; this could create a heavy burden on health care. Choosing the best designs for dose–response studies will help reduce the risk of recommending an incorrect dose for a new drug.

Dose-Ranging Studies: Design Considerations

Qiqi Deng and Naitee Ting

Department of Biostatistics and Data Sciences, Boehringer-Ingelheim Pharmaceuticals, Inc., Ridgefield, Connecticut, U.S.A.

Abstract

In the process of drug discovery and drug development, understanding the dose response relationship is one of the most challenging tasks. It is also critical to identify the right range of doses in early stages of clinical development so that Phase III trials can be designed to confirm some doses within this dose range. Usually at the beginning of Phase II, there is not a lot of available information to help guiding the study design. At this stage, Phase II clinical studies are needed to establish proof of concept (PoC), to identify a set of potentially effective and safe doses, and to estimate dose-response relationships. Challenges in designing these studies include: selection of the dose frequency and the dose range, choice of clinical endpoints or biomarkers, and use of control(s), among others. Consequences of bad Phase II study designs may lead to the delay of the entire clinical development program or the waste of R&D investment. Misleading results obtained from poor designs could cause a Phase III program to confirm a wrong set of doses, or to stop developing a potentially useful drug. Therefore, it is critical to consider an entire drug development plan, to make best use of all the available information, and to include all relevant experts in designing Phase II dose response clinical trials. This presentation discusses some of these considerations.

Keywords: Clinical trial; Design; Dose ranging; Dose response; Dose spacing; Phase II.

1 BACKGROUND

Typically, Phase I clinical trials are designed to evaluate escalating doses in order to find the maximum tolerable dose (MTD) so as to establish the upper anchor of doses for future development of new medicinal products. After Phase I, one of the most important objectives for Phase II clinical development is to answer the “Go/No Go” question – proof of concept. For new drugs treating non-life-threatening diseases, the next important objective is to establish the “dose range.” A range of doses can be identified by the high dose and the low dose, and the high dose is limited by MTD. As such, a key Phase II objective is to find a low dose of this dose range. Usually this low dose is considered as minimum effective dose (MinED). Simply put, Phase I is moving doses upward to find MTD; Phase II is moving doses downward to find MinED.

After the concept is proven, the most important next step is to explore and recommend the commercial doses to be tested in large phase III confirmatory clinical trials. PoC is usually faster and cheaper as it only requires a well-tolerated dose of test therapy plus the placebo (control) group. A dose-ranging study, however, needs multiple doses of the test therapy to characterize the dose-response relationship. Therefore, a classical phase II development program usually consists of small scale PoC trials followed by moderately sized dose-ranging studies.

Conceptually, the efficacy of a candidate product increases as the dose increases (Fig. 1). The left curve plotted in Fig. 1 can be viewed as an efficacy–response curve, with the response (y-axis) representing some measure of product efficacy. In addition to efficacy response, toxicity dose–response curves should be considered. We will assume, as shown in Fig. 1, when dose increases, both efficacy and toxicity increase. Based on these curves, the maximum effective dose (MaxED) and the MTD can be found: MaxED is the dose above which there is no clinically significant increase in pharmacological effect or efficacy; MTD is the maximal dose acceptably tolerated by a particular patient population. Ideally speaking, it is desirable that MTD is much higher than MaxED. In this case, any dose that is at or above MaxED, but much lower than MTD can be recommended as a labelled dose. Unfortunately, this is not the common case in most of drug development programs. When MaxED is above MTD, and that if the MTD was correctly estimated, the decreased dose from MTD usually lead to decreased treatment effect on efficacy, but also likely better tolerability, then the recommendation for phase III doses need to be based on a careful evaluation of benefit and risk.

In certain products, the efficacy curve and the toxicity curve are widely separated. When this is the case, there is a wide range of doses for patients to take; that is, as long as a patient receives a dose that is greater than

Fig. 1 Efficacy and toxicity dose response curves

the minimum effective dose, and below a toxic level, the patient can benefit from the efficacy while avoiding certain toxicities from the test product. However, for other products, the two curves may be very close to each other. Under this situation, physicians have to dose patients very carefully so that while benefitting in efficacy, patients do not have to be exposed to potential toxicity from the candidate product.

The area between the efficacy and the toxicity curve is known as the “therapeutic window.” One way to measure the therapeutic window is to use the “therapeutic index (TI).” TI is thought of as the ratio of TD_{50}/ED_{50} , where TD_{50} is the dose that produces 50% of maximum toxicity and ED_{50} is the efficacious dose that produces 50% of maximum treatment effect. Clearly, a product with a wide therapeutic window (or a high TI) tends to be preferred by both physicians and patients. We want the drug to have sufficient efficacy with the smallest dose in order to lessen or minimize side effects (even when the dose is on the low side). If a test product has a narrow therapeutic window, then it will need to be developed carefully. Caution is needed should the medicine be approved and prescribed in the target population.

Frequently, products developed for life-threatening diseases (e.g., cancer) tend to have narrow therapeutic windows. In contrast, products developed to treat chronic diseases (e.g., high blood pressure, depression, high cholesterol, or arthritis) are required to have wide therapeutic windows, because these products are frequently used in older patients with other concurrent diseases, and sometimes used in children.

In clinical development, Phase III trials are designed to confirm product efficacy. Results obtained from Phase III studies provide evidence to help regulatory agencies make decisions to approve or not to approve the candidate product. Therefore, it is critical that dose-ranging trials from Phase II deliver the information to help with Phase III design. In other words, if the appropriate dose or doses for product registration is not included in Phase III trials, it is likely that the compound will miss the opportunity of being approved for marketing. Hence information obtained from Phase II dose-ranging trials need to provide sufficient support for dose selection in Phase III study designs.

2 FINDING MINIMUM EFFECTIVE DOSE (MINED)

Minimum effective dose (MinED) is a crucial concept in product development. Unfortunately, there is no universally accepted definition of this term (Thomas and Ting, 2009).^[1] Finding MinED is critical because it is generally believed that toxicity increases as dose increases. Hence a lower dose that is effective implies it could be safer than higher doses.

Clinical results obtained from Phase III studies are used to support product registration. Based on these data, if a dose is efficacious and safe, then that dose can be approved, and the product label specifies the dose or the range of doses the product is approved for. Nevertheless, after approval, if excessive adverse events are observed from the low dose of the product, then a question as to whether this low dose is low enough could be raised. At this time, it would be very challenging to ask what is the MinED for this product. Therefore, it is critical to find MinED in Phase II, before it is too late.

Drug price in US is not directly associated with dosage. However, in many other countries, the price of a medicinal product is linked to its dose. In other words, if the dose of the product is higher, then it is more expensive. Now suppose a certain product is approved in such a country, and the price is set based on the lowest approved dose. If later it was detected that the MinED for the product is, in fact, lower than the approved dose, then a dose reduction is needed at a post-market stage. Accordingly, the price of this product at a lower dose may have to be further lowered as well. When this happens, there is a huge impact on the earnings from such a product. Therefore, from a marketing strategy point of view, it would be very critical to identify the MinED before the product enters its Phase III development.

MinED Finding is performed in the practice of Phase II trial. As discussed previously, if MinED was not identified at Phase II, it would be very difficult and very expensive to find the MinED at a later stage of product development. In fact, Phase II studies may be the only opportunity to characterize the relationship between doses and product efficacy. Therefore, it is vital to pay more attention to Phase II and to carefully design dose-ranging clinical trials during this critical phase of clinical development for a new product.

Although there is a definition of MinED from ICH E4 (1996)^[2] – “MinED is the **smallest dose with a discernible useful effect**”, the interpretation and implementation of such a definition varies a lot in practice. The first question is the understanding of “a useful effect.” It is difficult to achieve consensus about the smallest magnitude of an effect that is useful. One approach is to follow a well-established treatment effect such as lowering 5 mmHg of blood pressure in developing an antihypertensive product. Another is to consider the concept of minimal clinically

important difference (Farrar et al 2001,^[3] Katz et al, 2015,^[4] Osoba et al, 1998,^[5] and Rosen et al. European Urology 2011^[6]), the magnitude of the treatment effect above and beyond placebo effect is large enough to be perceived by a subject.

The implementation of a “discernible” effect could be even more difficult. Typically a “discernible” effect could be referred as a “statistically significant” difference from control. Under this interpretation, various authors recommend different ways of calling a dose as MinED based on the difference in treatment effect from a given dose as compared with placebo. Some researchers suggest the use of a dose-response model to help estimate MinED (Fillon, 1995^[7]; Pinheiro, et al, 2006^[8,9]). In the modeling approach, a treatment difference (δ) against placebo is proposed and from the model, if there is a dose achieves such a δ , then this dose is considered as the MinED.

Others (Hochberg and Tamhane, 1987,^[10] Wang and Ting, 2012^[11]) suggest the use of pairwise comparisons. Under pairwise comparisons of each dose vs placebo, a point estimate and an interval estimate can be calculated. Another commonly considered approach is William’s test based on isotonic regression (William, 1971,^[12] 1972^[13]). In William’s test, the mean of each dose group will be estimated under the monotonic order restriction. And the lowest dose, from where on the estimated effect at or above are all statistically significant from placebo, is considered as the MinED. Depending on the definition of MinED, these estimates are used to help proposing a dose as MinED. Even among those authors recommending use of pairwise comparisons to find MinED, there could be many differences, too. For example, some may argue that multiple comparison adjustment could be necessary, others may not. Whether or not multiple comparisons are needed, the understanding of “a dose that delivers treatment effect which is different from placebo” could still vary substantially, depending on individual’s point of view.

For example, let the useful effect be denoted as δ ; then, for a given dose, a point estimate and a confidence interval can be constructed for δ . If a positive value indicates a benefit effect, then the treatment response of the given dose of the test product subtracted from the placebo response is expected to be positive. Hence it is hoped that the point estimate of the treatment difference could be as much as δ . This leaves a wide range of interpretations – for MinED, should that dose be such that the point estimate is greater than δ ? Should that dose be such that the lower confidence limit be greater than 0? Should that dose be such that the upper confidence limit be greater than δ ? Or should that dose be such that the lower confidence limit be greater than δ (McLeod et al. 2016^[14])?

The implementation of “the **smallest dose with a discernible useful effect**” is fraught with various interpretations and complexity, making the definition difficult to implement unambiguously. In practice, one feasible way of finding a MinED in a dose-ranging clinical trial

is to find a dose that is lower than MinED. Regardless of which practical definition the project team uses to identify MinED, suppose there is a dose deemed to be “not efficacious,” and another dose that is higher could be considered to be “efficacious.” Then it can be considered that the non-efficacious dose is below MinED and the efficacious dose is above MinED. From a practical point of view, this information would usually be sufficient to help the team to design Phase III clinical trials.

Of course in the selection of Phase III doses, many other aspects will also have to be considered—such as safety or toxicity findings, pharmacokinetic properties, formulations, and so on. But the information about MinED would be one of the most critical deliverables from Phase II in supporting any Phase III development plans.

3 A MOTIVATING EXAMPLE

In a clinical development program for a test drug to treat osteoarthritis, the first dose response study included placebo, 80 mg, 120 mg, and 160 mg of the test drug (Ting, 2009^[15]). Results from this study indicate that all three doses are efficacious (Fig. 2a). These results also show that 80 mg may have already been at the high end of the efficacy dose-response curve. A second study was designed to explore the 40 mg dose, and results from this second study are given in the middle panel of the Fig. 2 (Fig. 2b). With these findings, the project team started Phase III studies using a dose range of 40 mg to 120 mg to confirm the long-term efficacy of this test drug.

An End-of-Phase II meeting with the Food and Drug Administration (FDA) was held after the long-term Phase III study started. FDA commented that the minimum effective dose (MinED) was not yet found. Hence the project team designed a third dose-response study to explore the lower dose range. Doses included in the third study are 2.5 mg, 10 mg, and 40 mg. As shown in the bottom panel of the Fig. 2 (Fig. 2c), the third study successfully established the dose-response relationship. Based on these results, it is clear that the Phase III studies were designed with a range of doses that are too high. The impact of this process can cause a major delay in the development program and considerable waste of resources.

4 HOW WIDE A RANGE OF DOSES TO STUDY?

The key lesson learned from this osteoarthritis drug development program is that a very low dose was not explored in early Phase II. In other words, if a dose at or below 10 mg was explored in the first study, a narrower dose range could have been established using a second study. Then the Phase III studies could have been designed with the appropriate dose range.

Fig. 2 Dose Response Results from the Three Studies of Osteoarthritis Drug

In general, the most difficult challenge in designing the first dose ranging trial in developing a new intervention is the selection of doses to be included in this design. The dose-ranging study is designed with two very important assumptions:

1. The maximal tolerated dose (MTD) was correctly estimated from earlier trials and
2. Efficacy response is monotonic to ascending doses.

However, it is unclear what range of doses to choose for efficacy activities. At this stage, the best guidance available is data obtained from pre-clinical experiments or from Phase I biomarkers. Even under the assumptions that the MTD was correctly estimated and there is a monotonic efficacy dose-response relationship, there can still be many possible shapes of dose-response curves.

Figure 3 presents an example of three dose-response curves. The three curves on this figure represent dose projections based on three animal models from non-clinical studies. One curve represents a dog model, another is a mouse model, and the third is from a rabbit model. The vertical dashed grey line (at the right side of Fig. 3)

Fig. 3 Several Possible Dose Response Curves

represents the maximum tolerated dose (MTD). The question then becomes, what range of doses should be considered in the upcoming dose-ranging clinical trial? From this perspective, the primary challenge in the dose-ranging trial design is to consider which range of doses needs to be studied.

4.1 Definition of Dose Range in a given study

Dose range in a clinical trial design is defined as the ratio calculated as the highest dose divided by the lowest dose included in the same design. For example, if the doses in trial A are placebo, 20 mg, 40 mg, and 80 mg, then the dose range is 4 ($= 80/20$). If the doses in trial B are placebo, 0.1 mg, 1 mg and 10 mg, then the dose range is 100 ($= 10/0.1$). Although the doses used in trial A are higher than doses used in trial B, trial B has in fact a much wider dose range – 25 times wider than trial A.

Given the discussion in the previous sections about MinED, it is critical to realize that in the first dose-ranging design, a wide dose range need to be studied. The high dose is typically set at MTD or a dose below MTD to avoid any potential toxicity. The real design challenge is to choose the lowest dose for this dose-ranging trial. If there is an interest to identify a dose that is below MinED, then the difficult question would be “how low would it be low enough?” Once the low dose is selected for the design, a dose range can be calculated as the ratio of the highest dose divided by the lowest dose.

4.2 Binary dose spacing

Hamlett *et al* (2002)^[16] propose to use a binary dose spacing (BDS) design for dose allocation. If the trial includes 2 dosing groups and a placebo, then the BDS design identifies a mid-point between the placebo and the MTD and allocates one dose above and another below the midpoint. If the trial includes 3 dosing groups and a placebo, then the BDS design identifies the high dose as described in the 2 dose case. A second midpoint is then identified between the placebo and the first midpoint, and a low dose is selected below the second midpoint and the medium dose is selected between the two mid-points. The BDS design

iteratively follows this strategy with more dosing groups. The BDS design employs a wide dose range, helps identify the MinED, employs a log-like dose spacing strategy avoiding allocating doses near the MTD (i.e., identifies more doses near the lower end), and is flexible and easy to implement.

5 PARALLEL CONTROLLED FIXED DOSE DESIGNS

Typical dose ranging trials are designed with parallel dose groups plus a placebo control. Patients are randomized to each treatment group and receive study medications for the entire duration of the study. For example, in a four treatment group design with four weeks duration, the doses are placebo, low dose, medium dose and high dose, then a patient is randomized into one of these four groups and will receive the same dosage of study medication from after randomization to week 4. A parallel design indicates that at the time a patient is recruited, the opportunity of randomizing into each dosing group is dictated by the study design, and that there is no requirement for any study dose to be before, or after another study dose.

Dose escalation designs are frequently used in Phase I. In a dose-escalation design, a group of subjects started with the lowest designed dose. After these subjects complete the lowest dose and there is no safety concern, then a different group of subjects will receive a higher dose. If this dose is well tolerated, then a third group of subjects will receive an even higher dose. This process continues until the stopping rule is met. A typical stopping rule would be some kind of pre-specified adverse events. In oncology, the stopping rule could include a dose limiting toxicity (DLT). In other words, if several subjects experiencing DLT's then it can be claimed that the MTD was exceeded. Dose escalation designs are very useful in finding maximally tolerable dose (MTD). However, because the duration of each treatment period is relatively short, these designs are not used in clinical efficacy trials. Phase II dose ranging trials are designed to study drug efficacy and, in most of therapeutic areas, drug efficacy can only be observed after a reasonable treatment period. Hence dose escalation designs are not used in dose-ranging trials.

A fixed-dose design and a dose-titration design are in contrast to each other. In a fixed-dose design, once a patient is randomized to a dose group, the patient would take the same dose of study product throughout the complete dosing period. In a dose-titration design, in contrast, a patient is randomized to a dose regimen with a starting dose, where the dose for a patient can be changed over time. In a titration design, patients are randomized to regimens, instead of doses. The regimen could be a 10 mg–20 mg test drug vs placebo. In this case, a patient could be randomized to test drug or placebo. If the patient is randomized to test drug, he or she would be dosed at 10 mg or 20 mg

of test drug, depending on study design. If a patient is randomized to placebo, then this patient may receive 10 mg matching placebo, or 20 mg matching placebo, according to the double-blind study design.

Dose-titration designs include forced titration, and response guided titration. For example, in an eight-week study with forced titration of test drug against placebo, with 10 mg and 20 mg dosages, then the design may dictate that every patient starts with 10 mg of test drug or matching placebo. Then after two weeks of 10 mg (or placebo) double-blind treatment, every patient will be titrated up to 20 mg, until end of treatment (week eight). On the other hand, a response guided titration design (again, two treatment groups with test drug against placebo, and eight weeks duration) would randomize patients into one of the two treatment groups, and every patient starts with 10 mg (or matching placebo). Then, depending on patient response, if the efficacy is not sufficient, then the treating physician may consider titrate the dose up to 20 mg. However, after the patient on the 20 mg dose, if there is safety concern at this dose, then the physician may down titrate the dose back to 10 mg. Hence dose-titration designs can be viewed as two different types – forced titration or response guided titration.

There are some advantages of a titration design. For example, a study with this design will allow a patient to be treated at the best dose for that specific patient; this dose allocation feature reflects the actual medical practice. However, the disadvantage of a titration design is the difficulty in data analysis. For example, if a patient responded to the test drug after doses are titrated up, it is unclear whether the higher dose delivered the efficacy or the accumulation of lower doses caused the response. In titration designs with multiple treatment groups, there may be overlapping doses as when, for example, one treatment group is 10 mg escalating to 20 mg, while another group is 20 mg escalating to 40 mg. When this is the case, it is difficult to make inferences about the 20 mg dose group.

In some rare cases, instead of a dose-response study, a concentration response study could be considered. A concentration response study assesses efficacy and safety measurements observed from subjects according to the plasma concentration of the study drug but not the doses of the study drug. There are many practical limitations in using this type of designs. These limitations include, among others, how to blind the patient and the physician and also how and when to measure the blood concentration. Because of the issues with dose-titration designs and concentration response designs, the parallel, fixed dose designs are, in general, the more commonly used designs for dose-ranging studies. Therefore, in many of the dose-response studies, patients are randomized to a few fixed-dose groups and are compared with one or more control treatment groups.

In Phase II dose-ranging clinical trials, the primary objective is to evaluate drug efficacy of each studied dose, and hence the most useful design is the parallel, controlled,

fixed dose design. In these designs, each patient is randomized to a pre-specified dose and followed for the designed study duration. During the entire study period, patients received the same dosage of the double-blind medication. Results obtained from these studies can be used to help understanding drug efficacy associated with each studied dose. It is important to note that dose-escalation design, dose-titration design, and concentration response design, cannot be used for efficacy dose-response purposes.

6 NUMBER OF DOSES AND CONTROL GROUPS

As discussed in the previous sections, a wide dose range is critical in the phase II dose-ranging studies. Once MTD is estimated from earlier studies and a wide dose range is considered, the natural questions to think about is how many doses should be included in the study and whether a placebo control group is sufficient or an active control group is needed.

A single high dose plus a placebo arm design may be able to demonstrate the proof-of-concept but cannot adequately characterize the dose-response relationship. Any attempt to interpolate a dose-response relationship between the placebo and the test dose would require very strong assumptions, which often times are not realistic. Therefore, a dose-ranging study typically needs several test dose levels. Generally speaking, it would be desirable to have more than two test doses plus one placebo arm in defining the dose-response relationship and estimating the difference of the test doses vs. placebo. One very commonly used design is a four-group study with placebo, low-dose, medium-dose and high-dose groups of the drug candidate under development.

Some authors suggest that more doses could help (Krams et al 2003)^[17]—that is, in the first dose-ranging study, adding more doses to the study design. However, the number of doses to be used in a dose-ranging trial is usually limited by practical and logistical considerations, such as available formulations of test doses, dosing frequencies, convenience for outpatients to use on their own, and blinding complexity. In some situations, an active control is also employed in a dose-ranging trial. Given the multiple treatment groups already included in a study, it may not be practical to add very many test doses into the same study.

In an early Phase II dose-ranging trial design, typically the total sample size is limited depending on budget, ethical concerns, availability of patients, and difficulty in recruitment. Under this circumstance, more treatment groups in a design imply fewer patients per treatment group. A smaller sample size of each treatment group provides a less precise estimate of treatment effect. Hence merely adding dose groups to a study design does not necessarily make the design to deliver more informative results. A well-thought through design strategy is needed before the number of dose groups can be determined.

In our opinion, for the first-dose ranging study design, it is more important to cover a wide dose range, than simply adding more doses to cover a narrow range of doses. This suggestion is both practical and sound. In practice, a trial with 4 to 5 test doses, plus a placebo control (a total of 5 or 6 treatment groups), will deliver a good understanding of where the test medication is most active, if the dose range is wide enough and the dose spacing is reasonable. Some simulation studies (Yuan and Ting 2014^[18]) suggest that, among the number of treatment arms (4, 5, 6, or 7, including placebo), it looks like three test doses (the 4-arm design) could be insufficient in some cases. The performance increases when more than three doses are studied. Similar conclusion was made in PhRMA adaptive dose-finding working group white paper (Bornkamp et al 2007^[19]). Given the same sample size, although four-arm studies with three active doses and placebo give more information for each pairwise comparison in secondary analysis, the power for the primary analysis based on contrast test provided in section 7 are usually comparable. In order to provide adequate coverage with reasonable spacing for a wide dose range, three-arm study is discouraged for dose-finding trials, and 4–5 doses are recommended.

On the other hand, six test doses (the 7-arm design) may not necessarily deliver better results than the four test doses (the 5-arm design) or five test doses (the 6-arm design) comparisons. When the total sample size is fixed, the 7-arm design offers a smaller sample size per group when equal sample size is used, and the precision on the treatment effect would be sacrificed. In this case, it may be a good idea to consider an unbalanced sample size allocation, for example by allocating more subjects to highest dose and placebo arm. Therefore, from a practical point of view, a dose-ranging design including four to five test doses (in addition to placebo), which cover a wide dose range, may be very useful in designing the first-dose ranging clinical trial.

7 SAMPLE SIZE CONSIDERATIONS

Whenever sample size calculation is needed for a given study, the first point is to understand the hypothesis to be tested. In the design of a Phase II dose-ranging clinical trial, the statistical hypothesis associated with such a trial is typically a proof-of-concept (PoC) hypothesis. In the case when a Phase II PoC study designed with only two treatment groups, a placebo group is compared with the MTD of study product, the hypothesis can be expressed in a straightforward fashion – responses from the test treatment is compared against responses from placebo. If the comparison is based on treatment means, then the hypothesis can be written as

$$H_0: \mu_T = \mu_P \text{ vs } H_1: \mu_T > \mu_P,$$

where μ_T is the test treatment group mean and μ_P is the placebo treatment group mean.

In other words, if mean responses from the test treatment group is statistically significantly improved than the mean responses from the placebo group, then the concept is considered proven.

However, in a dose-ranging trial design, the primary hypothesis is not straightforward. In this case, the trial includes more than two treatment groups. A typical dose-ranging design consists of the highest dose of the test product (could be the MTD) on the upper end, and of the zero-dose group in the form of placebo. Additionally, such a design includes one or more different doses in between these two extreme treatment groups. Under this circumstance, two possible options could be considered in specifying the primary hypothesis. One option is to keep the hypothesis the same as that in the two-group setting – namely, only test the highest dose (may be the MTD) against placebo.

Another option is to use a contrast which includes more than two treatment groups in order to perform the primary hypothesis test. If the second option is selected, then there could be many varieties in writing such a contrast.

For example, in a four-group design with placebo, low dose, medium dose and high dose, let μ_L be the mean response of low dose, μ_M be the mean response of the medium dose, and μ_H be the mean response of high dose. The contrast can be a trend test based on all doses (Wang and Ting, 2012^[11]; Ting, 2009^[15]) assuming monotonic dose-response relationship:

$$H_0: -3\mu_P - \mu_L + \mu_M + 3\mu_H = 0 \text{ vs } H_0: -3\mu_P - \mu_L + \mu_M + 3\mu_H > 0$$

Another possible proof-of-concept contrast may also include (which assumes all test doses are equally effective) is

$$H_0: -3\mu_P + \mu_L + \mu_M + \mu_H = 0 \text{ vs } H_0: -3\mu_P + \mu_L + \mu_M + \mu_H > 0$$

Alternatively, it can be assumed that only the high dose is effective:

$$H_0: -\mu_P - \mu_L - \mu_M + 3\mu_H = 0 \text{ vs } H_0: -\mu_P - \mu_L - \mu_M + 3\mu_H > 0$$

As can be found from these sets of hypotheses, if a contrast (which includes more than two treatment groups) is used for the statistical hypothesis, there could be many possible ways of writing such a contrast. As long as the contrast coefficients sum up to zero, (e.g., in the first example, $-3 - 1 + 1 + 3 = 0$), the rejection from the contrast test mentioned above will imply the rejection of the null hypothesis that all treatment arms are equal.

Once the statistical hypothesis, the clinical difference (after adjusted for standard deviation), and the corresponding alpha (α) and beta (β) have been determined, sample size for a given dose-ranging trial can be calculated.

Based on the above discussion, the sample size for a given contrast test can be calculated using the following formula (Chang and Chow, 2006^[20]).

$$n = \left[\frac{(z_{1-\alpha} + z_{1-\beta})\sigma}{\delta} \right]^2 \sum_{i=0}^k \frac{c_i^2}{f_i}$$

where

n is the total sample size of all treatment groups combined,

$z_{1-\alpha}$ and $z_{1-\beta}$ are the critical values of the standard normal distribution corresponding to Type I and Type II error, respectively,

δ is the treatment difference between test product and placebo,

σ is the standard deviation,

f_i is the fraction of number of patients in treatment group i ,

c_i is the contrast coefficient that is associated with treatment group i , it is assumed to have k dose groups plus placebo, where i is denoted as the 0 dose group.

In the calculation of sample sizes for a dose-ranging study, two popular types of patient allocation are possible: (1) balanced allocation where each treatment group receives an equal number of patients and (2) imbalanced allocation where the highest dose and the placebo groups receive more patients and other dose groups receives fewer patients per group. The sample size formula given here works well with either type of patient allocation. Examples of these types of allocation can be found in Yuan and Ting (2014),^[18] as well as Deng and Ting (2016).^[21] The above formula applies to cases where the primary endpoint is a continuous variable. In fact, sample size formula based on other types of response variables such as binary or time-to-event can also be found in Chang and Chow (2006).^[20]

Contrast test can be viewed as a test on the weighted average of all treatment arms, where the weight (i.e., the contrast coefficient) can be optimized for a certain known dose-response curve to maximize the power. However, a set of weights that is optimal for one dose-response curve may perform poorly for another. At the design stage of the first dose-ranging study, very little is known for the dose response shape and therefore it is important that the method for PoC is robust to model uncertainty. There are two robust approaches can be suggested to consider.

7.1 Ordinal Linear Contrast Test (OLCT)

An OLCT is expressed in terms of an ordinal linear contrast under a statistical null hypothesis (Wang and Ting 2012, Deng and Ting 2016). For trials including placebo and three doses of test drug, the contrast coefficients chosen are $(-3, -1, 1, 3)$. For trials with different number of treatment groups, the associated contrast coefficients are provided in Table 1. Since OLCT combines all the data

Table 1 Coefficients to be used in contrast for OLCT

Number of Doses plus Placebo	Coefficients						
	Placebo	Lowest Dose	Doses increase from left to right				Highest Dose
Two Doses	−1	0					1
Three Doses	−3	−1	1				3
Four Doses	−2	−1	0	1			2
Five Doses	−5	−3	−1	1	3		5
Six Doses	−3	−2	−1	0	1	2	3

available, and allocates the entire alpha to a single contrast test, it is in general a powerful test. In addition, OLCT can be viewed as a model-free test based on ranks. The weight for each arm is set to be proportional to the order of the expected responses for the different treatment groups. This method is robust to various dose-response shapes under monotonic assumption and also mild non-monotonic curves. For binary response, OLCT is very similar to the Cochran-Armitage trend test (Neuhauser and Hothorn 1999^[22]). It is important that an equally-spaced ordinal score should be used instead of the actual dose.

7.2 MCPMod

MCPMod stands for Multiple comparison procedures and modeling (Pinheiro et al 2006^[9]). The procedure starts with a specification of a set of different candidate models that covers a wide range of dose-response shapes. For each candidate model, the optimal contrast can be calculated. Since there will be a number of contrast tests, one for each candidate model, the multiplicity will be subsequently adjusted using multivariate *T* distribution. This multiplicity adjustment takes into account of the similarities between candidate models, which is reflected by correlation of contrast coefficient. Therefore, when similar dose response models are included, the multiplicity penalty is small. MCPMod will reject the null hypothesis of a flat dose response curve when at least one of the candidate models is significant after multiplicity adjustment. Extensions of MCPMod beyond normally distributed endpoints are available, including binary, count, longitudinal and time-to-event data (Pinheiro et al., 2014^[23]).

Under MCPMod, doses and patient allocation to different arms can be optimized according to different criteria: 1) D-optimal design minimizes the variance of the model parameters and 2) TD-optimal design minimizes the variance of estimation for target dose (Dette et al 2008^[24]). For more details regarding MCPMod, readers are encouraged to refer to the chapter “Dose Response Clinical Trials – MCPMod Approach” in this book.

In general, the contrast based approach including OLCT and MCPMod provide greater power advantages comparing to pairwise approach when the number of doses increase. Details of sample size calculation based on other

methods, for example William’s test for Minimum effective dose, are provided in Chang and Chow (2006,^[20]), and Chow et al (2003,^[25]).

8 DISCUSSION

There are many challenges in designing the first dose-ranging clinical trial. Two main problems are apparent. First, there is not much of information about the efficacy of the candidate product available. Second, too many answers are expected for this trial to deliver. Project team members tend to anticipate such a study will establish the PoC, identify the MinED, characterize the dose-response relationship, and recommend doses for Phase III designs. Fundamental statistical training points out that the best design is that one study answers one question. Hence the nature of a dose-ranging trial makes it a very difficult design in order to address many scientific questions, and with sparse information available before the study design stage.

In fact, there should be a logic sequence of thinking in addressing these relevant questions. The first step is to consider how wide a dose range should be – which is the most critical step. As a way to approach this question, information about the candidate under development, other marketed drugs in similar class, the indications this study is designed for, the target product profile, and characteristics of the primary endpoint, as well as other considerations, can all contribute to help with a better understanding of the potential dose range need to be explored. In practice, it is also important to have a good understanding of dosing frequency (from Phase I results), formulation (from manufacturing), and other relevant issues.

After the dose range is determined, the next step would be to consider the number of treatment groups. Will there be a need of an active control? How many doses should be included in this design? What dose spacing should be considered? Basically speaking, a trial with 4 to 5 test doses, plus a placebo control, will deliver a good understanding of where the test medication is most active, if the dose range is wide enough, and the dose spacing is reasonable. Extensive simulations indicate that six or more test doses (in addition to placebo) design may not

necessarily deliver better results than the four test doses or five test doses (Yuan and Ting, 2014^[18]). A study design with too many doses may introduce additional complexities from practical and logistical points of view (e.g., formulation, blinding).

Sample size calculation is needed for almost every clinical trial. Considerations in sample size calculations for a dose-ranging trial are very similar to those for other trials. However, because the nature of a dose-ranging trial includes multiple treatment groups, this feature may cause some level of confusion, both to statisticians and to non-statisticians. Nonetheless, if the decision is to only use a single degree of freedom contrast test as the primary comparison, then the situation can be simplified and addressed successfully. In the case of one contrast, the two major challenges would be what assumptions of dose-response relationship the team is willing to make and sample size allocation, either a balanced approach (an equal number of patients per group) or an imbalanced approach (an unequal number of patients per group). After these decisions are made, the statistician would then follow up and calculate the sample size for the study.

Suppose a contrast with one degree of freedom is selected and the sample size allocation is determined, the typical sample size considerations such as choice of treatment difference and choices of alpha and beta can then be specified. With this information, sample size can be calculated using existing formula. The sample size using MCPMod approach can also be calculated using contrast test, with an adjustment for multiplicity introduced by different candidate models.

Finally, although the sample size is usually selected based on PoC part of dose-ranging studies, it is worth noting that estimating dose response, or identifying appropriate dose for phase III is considerably more difficult than proof-of-concept test (Bornkamp et al 2007^[21]). Therefore, dose-ranging study should include an assessment on the precision of target dose estimate. Carrying more than one dose into confirmatory phase may be advised to ensure a reasonable chance of covering an appropriate dose range in phase III.

Abstract

It is frequently the case in clinical research that subjects drop out of a study before completion, especially in the case of long trials. This entry discusses ways in which to plan studies that will minimize the dropout factor, and reviews methods of compensating for the missing-data problem that subjects dropping out can create in a clinical study.

Keywords: Dropout; Longitudinal studies; Missing data.

INTRODUCTION

In clinical studies, the length of time for a study can vary tremendously, ranging from a few days or weeks to possibly a few years. For example, in an osteoporosis trial, to illustrate efficacy, subjects must be followed for two to three years. During this time, it is often of interest to track subjects periodically in order to characterize their response to treatment throughout the study as well as to obtain subject information in case the subject should discontinue (or, in other words, drop out). Thus, most primary endpoints of interest are collected repeatedly. Studies that follow subjects over periods of time are referred to as “longitudinal studies” and the corresponding data as “longitudinal data.”

It is frequently the case in clinical research that subjects drop out of a study before completion, especially in the case of long trials. Reasons for dropout vary, from relocation to another city, to lack of efficacy, to having a safety concern. For subjects dropping out of the study, responses that were to be captured at time points after which they dropped out are of course lost. Because the objective of most analyses in clinical trials is to estimate or test for differences in treatment effects, the problem then becomes one of estimating or testing for these effects, taking into consideration subject dropout. In this case, there are two sets of variables to be considered in a trial: the clinical response variables (involving the parameters of interest) and the variables describing the dropout process (involving nuisance parameters).

Note: Material presented is based in part on the efforts of a working group at Pfizer Central Research, which produced the technical report “Selected Approaches for the Analysis of Longitudinal Data with Dropouts”.^[1]

OVERVIEW

Dropout is a special case of the missing-data problem. In the case of “dropout” in longitudinal studies, it is assumed that no measurements post-dropout are observed. As a result of this property, dropout is also sometimes viewed as a “monotone” or “truncation” missing data pattern. Although this article focuses on dropout, other patterns of missing data may be present in any given longitudinal study and the statistical methods discussed herein will remain applicable with perhaps some modification or supplementation. Work concerning inference in the presence of incomplete data in more general situations can be found in Rubin^[2] and Little and Rubin.^[3] References dealing specifically with the problem of missing data in longitudinal studies include Laird,^[4] Wu and Carroll,^[5] Wu and Bailey,^[6] Diggle and Kenward,^[7] Little,^[8] Hogan et al.,^[9] and Molenberghs and Kenward.^[10]

Before proceeding to the statistical frameworks and methods for handling dropout, it is important to highlight some broader considerations regarding missing data due to dropout in longitudinal studies. First, it is important to plan and conduct studies so as to minimize the potential for dropout. Components of studies that can have a significant bearing on the frequency of missing data due to dropout and can that be addressed before a study begins are inclusion and exclusion criteria, visit schedules, data capture methods, and the definition of endpoints themselves. In some situations provisions can be made for collection of efficacy or safety endpoints even after a subject has dropped out of the study proper. Some examples are a search of records for vital status or hospitalizations in cardiac studies and follow-up directly with subjects via a telephone call or written request for endpoint information.

Second, pre-specification of the method(s) to be used in the presence of missing data, and sensitivity analysis to assess the potential impact on the results, has become an expectation of regulatory agencies.^[11,12] Third, the ability to obtain unbiased estimates depends upon the analysis method in addition to the underlying dropout process. For example, the observed responses and covariates may theoretically contain all the information necessary to conduct an MAR analysis, but the ability to actually produce unbiased estimates depends upon identifying an analysis methodology/model to actually incorporate that information appropriately.

Lastly, the data that are observed might provide some information about the dropout process and perhaps about the data unobserved due to dropout, but it should not be assumed that such data will provide complete or conclusive information. This point will be revisited in the section “Other Methods.” For example, the observed data may indicate that the probability of dropping out is related to observed responses earlier in the study and thus indicate that the assumption of missing “completely at random” would not be appropriate. However, failure to identify a relationship between observed data and the probability of dropping out should not be taken as conclusive evidence that the dropout process is that of “missing completely at random” or “missing at random.”

In the next section we will explore various relationships between the measurement and dropout processes. Discussion of some general analysis methods currently used in the pharmaceutical industry and the implications of missing data in characterizing the response distribution (for example, estimating treatment effects) will be given in the section “Analysis Populations and Accompanying Methods.” Two parametric methods developed specifically for this problem will be discussed in the section “Other Methods.” The main focus of this entry is on the analysis of continuous data as the outcome variables, with emphasis on a univariate response measurement. Extensions will be mentioned in the “Discussion” section.

THE DROPOUT PROCESS

If all subjects remain in the study, the only process of interest is the distribution of responses, in other words, the measurement process. For example, bone mineral density may be the primary response variable of interest in an osteoporosis trial or glycosylated hemoglobin (HbA_{1c}) in a trial for diabetes. However, when subjects drop out we also need to consider the dropout process and its relation to the measurement process. Unfortunately, many of the current statistical procedures available for analyzing longitudinal data do not suitably incorporate the missing-data process and thus may lead to biased results.

In general, by the “missing-data mechanism,” we mean the distribution of the variable indicating whether each response is observed or missing. In the case of dropout, this sequence of variables remains constant (say, 1, indicating an observation as being observed) until the subject discontinues, at which point it changes to a new value (say, 0, indicating an observation as being unobserved). Therefore, this process can be characterized by the time a subject drops out. The effect this has on analyzing longitudinal data depends on the relationship between the dropout process and the subject response measurements. The reasons for the dropout of a subject may not depend on the response measurements, may depend only on the observed measurements, or may depend on the unobserved measurements. Different terminology is used by various authors. We will follow the terminology of Diggle and Kenward.^[7]

When the dropout is independent of the measurement process, then the dropout mechanism is termed “missing completely at random” (MCAR). An example would be a subject who drops out because he or she moves to a different city for reasons that have nothing to do with the disease or treatment. The case of missing completely at random also applies when the reason for dropout depends only on observable covariables. In other words, given covariables, subjects remaining in the study are a random subset of those dropping out of the study. Thus, any analysis that involves conditioning on these covariables (such as in a regression) will provide valid inferences with respect to the whole population being sampled. An important special case of this is differing dropout rates among treatment groups being compared, but the dropout being unrelated to the observed or unobserved responses.

When the dropout depends only on the observed portion of the measurement process (and covariables) but does not depend on the unobserved portion then the corresponding mechanism is termed “missing at random” (MAR). For instance, a subject who experienced less relief in prior treatment of a migraine headache may be more inclined to terminate a study than those who experienced greater relief. Again, in this case, the distribution of responses (adjusted for prior relief) for unobserved subjects is assumed to be the same as for observed subjects.

The preceding two types of dropouts are referred to as “noninformative” or “ignorable” dropout. When the dropout depends on the unobserved cases of the response measurements, the dropout is said to be “informative” or “nonignorable.” This is the case when dropout cannot be completely characterized by the observed information. Suppose a subject takes the study medication but continues to experience disease deterioration. Furthermore, the subject calls the office, briefly describes the problem, and never returns. This can be considered as a dropout for lack of efficacy, without corresponding response data collected. It is an example of dropout that depends on an unobserved response, or an informative dropout.

Analysis Populations and Accompanying Methods

It is customary to analyze data with dropouts based on specific subgroups of subjects. One simple subgroup is defined as such that data analysis is performed based on those subjects with the complete sequences of data collected over the study period. This is usually referred to as the “completers” subgroup analysis. Those subjects who drop out and therefore do not have data after dropping out will be excluded from the analysis. Inferences based on this population apply to the original population only in the case where subjects who have dropped out (dropped out completely at random) and any covariables affecting the likelihood of dropout are included in the analysis. This case is, in most circumstances, unlikely. Even in the case where missing completely at random holds estimates from a complete case analysis will be less efficient than when analyzing all the data.

Another approach is to base the analysis on all enrolled subjects, with any unobserved data being filled in (imputed) using some algorithm. Analyses involving all randomized subjects are usually referred to as intention-to-treat (ITT) analyses. The simplest imputation technique is to carry forward an observation obtained during the study such that every subject has a complete sequence of data values for every time point. Algorithms for carrying forward an observation include filling in missing values with the last observed response for a subject [last observation carried forward (LOCF)], with the worst observed response, or in some cases with the best observed response. (See the chapters “Carry-Forward Analysis” and “Imputation in Clinical Research” for more details.)

Obviously there are statistical concerns associated with these approaches. It is possible that subjects who dropped out were those who did not benefit from the treatment, did not tolerate the treatment well, or experienced serious side effects. Those who completed the study may have either had better health conditions or experienced greater benefit from the treatment to which they were assigned. In this case, a completers subgroup analysis is likely to err toward indicating an exaggerated positive effect for one or more of the treatments under study. In the case of an ITT analysis using longitudinal regression modeling paired with carried forward imputation, a further concern is the reduced variability estimates from imputing a single, fixed value.^[13] Observations to be collected after a subject’s dropout would have followed a certain distribution with a certain mean and variance. Imputing a constant value over time would reduce the underlying variance for each subject. Finally, it can be argued that imputation methods such as LOCF, baseline observation carried forward, and worst observation carried forward in effect change the hypothesis that is actually being tested inasmuch as the parameters being estimated have

a different interpretation from those being estimated if dropout does not occur.

A third approach is to perform statistical analyses based on the observed data, i.e., analyzing all of the subjects with any available data. The linear random-effects modeling method fits into this class. Under the linear random-effect model, each subject’s set of serial measurements is assumed to follow a linear function to time, with normally distributed errors. It is further assumed that the underlying slope and intercept of this individual linear function are bivariate normal random variables. The treatment effect is determined by the comparison of the slopes.^[14]

This procedure produces unbiased estimates in the case of ignorable dropout. However, the problems of bias and inefficiency in estimating treatment effect still exist when the unobserved data (i.e., after dropping out) contains information of the unknown treatment effect parameter; i.e., the dropout process is informative. For example, consider an analgesic study in which many subjects in a placebo group drop out due to inadequate pain relief, but a few remain because of a placebo effect or a higher tolerance for pain. In this case the placebo group efficacy may be overstated because the subjects who dropped would likely have had poorer outcomes; this in turn hinders the ability of the study to find a difference between an active agent and placebo.

Another all observed data approach is the likelihood-based mixed effects model repeated measures (MMRM) approach. The MMRM method uses an unstructured approach (e.g., serial measurements not assumed to follow a linear relationship) to modeling both the treatment-by-time means and the variances and covariances. This method has been shown to perform well assuming the dropout mechanism is MAR and has been argued to be preferable to LOCF analyses.^[15–17]

The applicability of the aforementioned methods depends on the missing-data process. Because none of the methods mentioned simultaneously consider the dropout process, none are suitable when the dropout mechanism is informative. Methods that model the joint distribution of response and dropout in terms of the marginal distribution of the response and the conditional distribution of dropout given response are called “selection model” methods.^[8] A variation of this model is the random coefficient-selection model or shared parameter model, where the response and dropout processes are conditioned on shared within-subject random effects.

Two such procedures will be described briefly in the next section: Diggle and Kenward^[7] and Wu and Bailey^[6] (for specific details the reader is referred to the corresponding papers). Diggle and Kenward’s approach is an example of the traditional selection model approach. Wu and Bailey’s methodology is an approximation of an approach developed by Wu and Carroll,^[5] which is an example of a shared parameter model.

OTHER METHODS

Diggle and Kenward

Diggle and Kenward proposed a likelihood-based method to adjust for informative dropout in analyzing continuous longitudinal data. As mentioned earlier, in order to adjust for dropout, Diggle and Kenward consider a selection model approach to model the joint distribution of response and dropout. Their approach can be broken down into three basic components: an underlying multivariate normal linear model to model the longitudinal response vector; a logit model to model the likelihood of dropping out as a function of the longitudinal responses; and the likelihood function of the observed data, which ties the first two components together. An application of the Diggle and Kenward approach to data from a clinical trial with dropout can be found in the text by Molenberghs and Kenward.^[10] We will describe these components in general next.

The longitudinal responses of individuals across time are assumed to have a multivariate normal distribution. In clinical trials, the primary interest is whether or not there is a treatment effect. The treatment effect as well as other covariates, such as the corresponding measurement time for a particular response, baseline status, and centers, are incorporated as parameters in a linear function describing the relationship with the mean response vector. For the covariance structure, Diggle and Kenward allow for three independent variance components: a random intercept component between individuals, a serially correlated within-subject component, and a sampling or measurement error component that is uncorrelated across individuals.

The dropout process is modeled by implementing a linear logistic model. The logit of the probability that the subject, at time d , drops out is modeled as a linear function of the responses prior to dropout and the unobserved response at the time of dropout. Assuming the underlying dropout and response models are correct, submodels can be fit and tested using the likelihood ratio statistic to determine if the dropout process is informative. Using the definitions for the various dropout mechanisms given in "The Dropout Process," the full model corresponds to a case of nonignorable dropout (dropout depends on unobserved data). The reduced model, where the coefficient associated with the unobserved response at the time of dropout is zero, corresponds to the case of ignorable dropout. In this case, the dropout process is independent of the missing response. Lastly, completely random dropout corresponds to the model where all coefficients except the intercept are zero. In this case, the dropout process is independent of both observed responses and missing responses.

For each subject, the observed data consist of the observed longitudinal responses prior to dropout and the time of dropout. Therefore, each subject contributes the following to the likelihood: the marginal distribution of the multivariate linear model corresponding to the responses

up to the time prior to dropout and a sequence of terms corresponding to the probability that a subject drops out at the time he or she did based on the observed responses.

For each subject, the log-likelihood function for (θ, Σ, ϕ) given the observed can be partitioned into three components: $L(\theta, \Sigma, \phi) = L_1(\theta, \Sigma) + L_2(\phi) + L_3(\theta, \Sigma, \phi)$

The first likelihood component is

$$L_1(\theta, \Sigma) = \log \{ \phi_{d-1}(y) \} \quad (1)$$

where $\phi_{d-1}(y)$ is the joint marginal multivariate normal density for the first $d-1$ observed longitudinal responses, where d is the time of dropout for the particular subject.

The second and third components correspond to the probability that a subject drops out at time d given the $d-1$ observed longitudinal responses. This consists of a sequence of terms corresponding to the probability that a subject does not drop out before time d and a term for the probability that a subject drops out at time d . This involves the following two terms:

$$L_2(\phi) = \sum_{j=2}^{d-1} \log \{ 1 - \Pr(j | \dots, y_{j-1}, y_j; \phi) \} \quad (2)$$

and

$$L_3(\theta, \Sigma, \phi) = \log(\Pr(d | y_1, \dots, y_{d-1}; \theta, \Sigma, \phi)) \quad (3)$$

where $\Pr(j | y_1, \dots, y_{j-1}, y_j; \phi)$ in Eq. (2) has the following form based on the logistic regression model for modeling the dropout process:

$$\Pr(j; \phi) = \text{logit}^{-1} \left(\phi_0 + \phi_1 y_j + \sum_{k=2}^j \phi_k y_{j+1-k} \right) \quad (4)$$

Only subjects who drop out of the study contribute to Eq. (3). Because the response value y_d at time d (time of dropout) is unobserved, it is not conditioned upon Eq. (30). Eq. (3) is evaluated by integrating Eq. (4) for $j = d$ over the univariate normal conditional distribution of y_d given $y_1, \dots, y_{d-1}$.

Parameters are estimated iteratively via maximum likelihood (ML) using the simplex algorithm of Nelder and Mead.^[18] Using maximum likelihood, the parameters of the complete-data model and dropout process are estimated simultaneously, and thus parameter estimates corresponding to the response distribution, such as treatment effects, are obtained adjusting for dropout (assuming suitable models for response and dropout have been found). In addition, it is possible to test certain hypotheses about the dropout mechanism by testing whether coefficients associated with various response measurements given in Eq. (4) are zero. As mentioned above, it is important to understand that such tests might indicate whether or not the *observed* data are consistent with a certain type of dropout mechanism, but fundamentally they cannot be used to conclude

that unobserved measurements are or are not related to what has been observed.

As mentioned earlier, a generalization of the selection model is the random coefficient-selection model. In this case rather than the marginal response and dropout process, we have the response and dropout process conditional on within-subject random effects. A special case of this is the shared parameter model, where the dropout process possibly depends on unobserved within-subject random effects underlying the response distribution and is thus informative.

Wu and Bailey

Wu and Bailey give a methodology to approximate the approach developed by Wu and Carroll. Wu and Carroll use a random-effects linear model and discrete time survival model to model the response and dropout process, respectively, where the likelihood of dropout during a specific time interval is a function of the dropout time and on the subject-specific intercept and slope. We begin with a specific form of general random-effects linear model of Laird and Ware.^[19]

Assume that for an individual of a particular group k , conditional on the underlying vector of coefficients β_k , the series of measurements $\mathbf{Y}_i$ follow a multivariate normal distribution with mean $\mathbf{X}_i\beta_k$, and variance σ^2 , where σ^2 is an unknown scalar residual variance, and β_k are random variables that are multivariate normally distributed with mean B_k and covariance matrix Σ_β , where $\mathbf{Z}_i$ is a $(q \times p)$ between-subjects design matrix, β is an unknown $(p \times 1)$ vector of slopes, and Σ_β is an unknown $(q \times q)$ covariance matrix. The linear random-effects model implies that marginally $\mathbf{Y}_i$ are independent multivariate normal with mean $\mathbf{X}_i\beta_i$ and covariance matrix $\mathbf{K}_i\Sigma_\beta\mathbf{K}_i^T + \sigma^2\mathbf{I}$, where $\mathbf{X}_i = \mathbf{K}_i\mathbf{Z}_i$.

Wu and Carroll consider the case where dropout is caused by a subject's death or withdrawal and refer to it as the "right-censoring" process. They assume that the series of measurements follows a linear random-effects model and that the right-censoring process and the observed data share the random-effects parameters β_k are also related to the probability of being right censored through a regression function such as probit or logistic. The corresponding marginal likelihood for B_k , the true group effect parameter, consists of the joint distribution of the simple least-squares estimates of individual intercept and slope, the unobserved true individual random effect parameters, and the right-censoring process, which is then integrated over with respect to the individual random effects parameters β_k . To obtain parameter estimates, the unknown scalar variance and the covariance matrix of the random intercept and slope are substituted with the unbiased estimates of them in the likelihood function, and with the observed survival times and censoring times the marginal likelihood is called a pseudo-likelihood.

Under noninformative censoring, the maximum-likelihood estimates of the random slopes β_i are the weighted least-squares estimates (WLE), which are just a weighted average of the individual simple least-squares estimated slopes, with $[\Sigma_\beta + (\mathbf{X}_i^T\mathbf{X}_i)^{-1}\sigma^2\mathbf{I}]^{-1}$, the inverse of the variance of the random slopes, as the weight. In this case, the WLE are consistent and unbiased.

However, when censoring is informative, for example, censoring depends on the individual slope so that subjects who have more serious outcomes (say, steeper rate) are more likely to drop out early, then the WLE are biased. This is because the weights used in the weighted least-squares estimation are functions of the within-subject design matrix, $\mathbf{K}_i$, which is a function of the number of repeated measures within the subject. Subjects who drop out early have smaller weights than those who drop out late or who complete the study, resulting in estimates that tend to reflect only the treatment effect of those with less serious conditions, which are thus biased. Note that because the individual ordinary least-squares estimates for slope are unbiased, if an unweighted average is used (UWLE) to estimate the random slope effect, then this estimate is unbiased, although it can be inefficient.

Wu and Bailey provided a simple approximate method for the informative censoring problem. They observed that under the random-effects linear model with a probit censoring process, the conditional expectation of the random-effect slope (given the censoring time) is a monotonic function of the censoring time. Thus, instead of modeling the censoring process, they assume that, given the censoring time, the individual least-squares estimated slopes are linear functions of the censoring time with normal errors. Specifically, the conditional linear model assumes that, for each individual, conditional on the censoring time, the expected random slope has mean $\gamma_0 + \gamma_1 E_k(T_i)$ and conditional variance σ_{kTi}^2 , where $E_k(T_i)$ is the expected value of censoring time for subject i in treatment group k . The conditional variance σ_{kTi}^2 is an unknown scalar residual variance, which depends on censoring time and thus on the number of measurements before dropout. Under the random-effects linear model, the σ_{kTi}^2 equals $\Sigma_\beta + (\mathbf{X}_{Ti}^T\mathbf{X}_{Ti})^{-1}\sigma^2\mathbf{I}$, and when Σ_β and σ^2 are unknown, they can be estimated using the restricted maximum-likelihood method (REML) method.

Two methods to estimate the random effect parameters under the conditional linear model are proposed. These are referred to as the linear minimum variance unbiased (LMVUB) and the linear minimum mean squared error (LMMSE) estimates, respectively. Because of the good properties associated with the first method, we will discuss it next and refer the reader to Ref. [6] for discussion of the second.

The LMVUB procedure estimates the conditional linear coefficients γ_0 and γ_1 by weighted least squares and then substitutes the estimates of γ_0 and γ_1 into the conditional linear function to obtain the LMVUB of B_k . The sample

mean censoring time is used as an estimate for $E_k(T_i)$, the expected value of censoring time for subject i in group k . In practice, the LMVUB estimator can be derived following a sequence of steps. First, the ordinary least-squares estimators of slope for each individual are obtained, and the conditional variances of the estimated conditional slopes given the design matrix of observation times are estimated. Then, weighted analyses of covariance based on these individual slopes, using the inverse of the conditional variances as weights, with dropout times as covariates in the linear model, are used to estimate the group slopes. The difference between the slopes is then tested for significance.

In a simulation study, using a probit model for the right-censoring process, the performance of the LMVUB procedure was competitive when compared to the pseudomaximum-likelihood estimation of Wu and Carroll. As also shown in a Monte Carlo simulation study by Wang-Clow et al.,^[20] which compares the performance of several estimators (UWLE, WLE, LMVUB, weighted mean, complete-case, and MLE), when the missing process is informative but the same in both treatment and control groups, the LMVUB is the only unbiased estimator for the difference of the slopes. When the dropout process differs for the two groups, the UWLE has the smallest bias, but it is noncompetitive in terms of mean squared error. The LMVUB has the smallest mean squared error and the lowest bias of all the estimators.

DISCUSSION

A key assumption of the dropout model proposed by Diggle and Kenward is that the process depends at most on the responses up to and including the unobserved response at the time of dropout but not the latter unobserved responses. Little^[8] mentions that such a dropout model is more plausible when dropout is linked directly to the response being measured (such as withdrawal to avoid a particularly invasive procedure) rather than to some underlying process (such as weight loss, nausea, somnolence, etc., because of treatment with a medication).

In the second case, the dependence of dropout on future unobserved responses is a function of how accurately the response variable measures the underlying process. In this case, the framework underlying the random coefficient-selection model may be better satisfied.

An alternative approach to the selection model is the pattern mixture model. In this case, the joint distribution of response and dropout is modeled as the marginal distribution of dropout and the conditional distribution of response given dropout. Because the data are not observed when missingness occurs, parameters underlying the response distribution given dropout are linked by specifying prior information. Little^[21] considers this type of model for analyzing incomplete multivariate data.

The text by Molenberghs and Kenward^[10] provides an introduction to and examples of selection and pattern mixture models; a Bayesian approach to estimating pattern mixture models in clinical trials with dropout has been explored by Demirtas.^[22]

EXTENSIONS AND SOFTWARE

In this entry we discussed the effect of dropout primarily in analyzing continuous longitudinal data. An example of a shared parameter approach when the longitudinal data are binary is given in Ten Have et al.^[23] An example of a random coefficient-selection model approach for ordinal longitudinal data, where dropout is a function of the response variable and within-subject random effects, is given in Sheiner et al.^[24] For extensions involving nonparametric analysis of incomplete repeated measures, the reader is referred to Wei and Johnson.^[25]

Lastly, software for running Diggle and Kenward's procedure using Splus (called "Oswald") can be found on the Internet;^[26] the use of the software was recently illustrated in the context of a psychiatric clinical trial with informative dropout.^[27] As far as we know, no available software exists for the Wu and Bailey procedure, but the steps outlined under "Wu and Bailey" can easily be implemented using existing statistical software. In addition, single imputation methods, such as LOCF, and multiple imputation methods can be carried out using the software package SOLAS.^[28]

Drug Development

Naitee Ting

Pfizer Global Research and Development, New London, Connecticut, U.S.A.

Abstract

The drug-development process can be broadly classified into two major components: nonclinical development and clinical development. This entry breaks down these two phases of drug development and considers regulatory requirements and marketing of a new drug.

INTRODUCTION

Most of the drugs available in pharmacies started out as a chemical compound or a biologic discovered in laboratories. When first discovered, each new compound or biologic is denoted as a drug candidate. The drug candidate has to demonstrate some activities in the laboratory to indicate that it has the potential of treating certain diseases in humans. Drug development is a process that starts when the drug candidate is first discovered and continues until it is available to be prescribed by physicians to treat patients with the disease. A potential new drug or a drug candidate can generally be classified into one of two categories: a synthetic chemical compound or a biologic. A compound is usually a new chemical entity synthesized by scientists from pharmaceutical companies (often referred to as sponsors), universities, or research institutes. A biologic can be a protein, a part of a protein, DNA, or a different form either extracted from tissues of another live body or cultured by some type of bacteria. In any case, this new compound or biologic will have to go through the drug-development process before it can be consumed by the public.

OVERVIEW

The drug-development process can be broadly classified into two major components: nonclinical development and clinical development. Nonclinical development includes all drug testing performed outside of the human body, and clinical development is based on experiments conducted in the human body. Nonclinical development can be further divided into pharmacology, toxicology, and formulation. In these processes, experiments are performed in laboratories or pilot plants. Observations from cells, tissues, or animal bodies are collected to derive inferences for potential new drugs. Chemical processes are involved in formulating the new compound into drugs to be delivered into the human body. Clinical development can be further divided into Phases 1, 2, 3, and 4. Clinical studies are designed

to collect data from normal volunteers or patients who participate in these studies.

Throughout the whole drug-development process, two scientific questions are constantly being addressed: Does the drug candidate work? Is it safe? Starting from the laboratory where the compound or biologic is first discovered, the candidate has to go through many tests to see if it demonstrates both efficacy (the drug works) and safety. Only candidates that pass all those tests can progress to the next step of development. In the United States, after a drug candidate passes all of the nonclinical tests, an investigational new drug (IND) document is filed with the Food and Drug Administration (FDA). After the IND is approved, clinical trials (tests on the human body) can then be performed for the drug candidate. If this drug candidate is shown to be safe and efficacious through phases 1, 2, and 3 clinical trials, the sponsor will then file a new drug application (NDA) with the FDA in the United States. The drug can be made available for general public consumption only if the NDA is approved. Oftentimes the new drug continues to be developed even after it is on the market. These postmarketing studies are known as phase 4 clinical trials.

A great many statistical methods are used in both clinical and nonclinical drug-development processes. Details of these processes and statistical applications are discussed in the following sections: The next section introduces the regulatory requirements. The following sections discuss “Nonclinical Development” and “Premarketing Clinical Development.” “Postmarketing Clinical Development” is presented next.

REGULATORY REQUIREMENTS

In most modern countries, a drug has to be approved by drug regulatory agencies before it can be marketed. For example, in the United States this agency is the FDA, in Canada it is the Health Protection Branch (HPB), etc. There are guidelines from these agencies to regulate various products and processes in drug development.

These guidelines provide a consistent framework for sponsors (pharmaceutical companies) to develop a new drug and for reviewers in these agencies to evaluate documents submitted to them by the sponsors.

The guidelines cover many aspects of drug research and development. For example, the guidance documents from the FDA regulate various steps of new drug development, including chemistry, pharmacology/toxicology, INDs, clinical/medical, information technology, labeling, generics, advertising, and other areas of drug regulation. Among all these guidance documents, the one that is most relevant to biopharmaceutical statistics is the “Guideline for the Format and Content of the Clinical and Statistical Sections of an Application,”^[1] within the clinical/medical guidelines. This document regulates the format, contents, data sets, and statistical methods used for both efficacy and safety analysis in an NDA report. For details of these documents, interested readers may refer to the FDA guidelines. These guidelines can be ordered from the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402. They can also be found from the following Web page: (<http://www.fda.gov/cder/guidance/index.htm>).

There has been a continuous effort to harmonize regulation guidelines from various countries. A new organization—the International Conference on Harmonization (ICH)—has arisen, with members from regulatory agencies and drug developers (or sponsors) of various countries (including the United States, Canada, Japan, and many other European and Asian countries), to generate a set of guidelines for drug developers and regulatory agencies to use. As of 1998, a number of ICH guidelines had been developed and finalized; other guidelines were being drafted. The ICH guidelines can be broadly divided into the areas of safety, efficacy, and quality. Statistics is an important component in these guidelines. In particular, ICH Efficacy Guideline E9—“Statistical Principles for Clinical Trials”—was developed specifically for statistical applications in the clinical development of a new drug.

NONCLINICAL DEVELOPMENT

A new chemical compound or biologic can be a drug candidate because it demonstrates some desirable pharmacological activities in the laboratory. At such an early stage of drug development, the focus is mainly on cells, tissues, organs, or animal bodies. Experimentation on human beings is performed after the candidate passes these early tests and looks promising. Hence, nonclinical development may also be referred to as “preclinical” development because these experiments are performed before clinical trials are performed on the human body.

One of the most important properties to be studied at the nonclinical testing stage is whether there is a dose–response relationship for the drug candidate. Fig. 1 shows

Fig. 1 Theoretical dose–response curves

two theoretical curves describing these relationships. The x -axis represents the doses of the drug candidate (can be linear scale or logarithmic scale), and the y -axis represents the responses. Suppose the y -axis allows 0% responses at the bottom and 100% responses (both efficacy response and toxicity response) at the top, then as dose increases, the responses increase. The curve on the left represents the desirable response (potency, efficacy); the curve on the right represents the undesirable response (toxicity). The area in between those two curves would be the doses at which the drug works and is safe. Theoretically speaking, the best drug candidate would be one for which the drug potency (efficacy) increases very rapidly while the toxic response does not increase much as the dose increases. Under this ideal situation, a wide range of doses can be prescribed to treat patients. However, in reality these two curves can be close to each other. When this is the case, there is a narrow range of doses that will be both potent and safe, and dose selection must be very careful. In the process of developing a certain drug candidate, should these two curves become too close to each other, or should the toxic response curve locate to the left of the efficacy curve, then the strategy may be to stop development for this candidate.

At the preclinical stage, the study of drug potency or efficacy is part of pharmacology, whereas the study of toxicity is part of drug safety. In addition to pharmacological activity and toxicity, another important process at this preclinical development stage is the formulation of the compound or biologic into a form that can be consumed by humans (for example, tablet, capsule). This process is generally referred to as “drug formulation.” Nonclinical development processes include pharmacology, toxicology/safety, and drug formulation. These processes are described in the following subsections.

Pharmacology

Pharmacology is the study of the selective biological activity of chemical substances on living matter.^[2] A substance has biological activity when, in appropriate doses, it causes

a cellular response. It is selective when the response occurs in some cells and not in others. Therefore, a compound or a biologic has to demonstrate these activities before it can be further developed. In the early stages of drug testing, it is important to differentiate an “active” candidate from an “inactive” candidate. There are screening procedures to select these candidates. Two properties of particular interest are sensitivity and specificity. Given that a compound is active, “sensitivity” is the conditional probability that the screen will classify it as positive. “Specificity” is the conditional probability that the screen will call a compound negative given that it is inactive.^[3] In the ideal case, both of these values should be close to 1.

The level of these pharmacological activities may be viewed as the drug potency or strength. The estimation of drug potency by the reactions of living organisms or their components is known as bioassay. According to Hubert et al.,^[2] “the experimental determination of the potency or strength of a chemical or biological substance based on the response observed after its administration to living matter (animal or animal tissue) constitutes a biological assay.”

As discussed previously, one of the most important relationships needed to be studied for pharmacological activities is the dose–response relationship. In these experiments, several doses of the drug candidates are selected, and the responses are measured for each corresponding dose. After response data are collected, regression methods may be applied to analyze the results. Regression modeling is a very useful statistical method applied in the analysis of pharmacological activities.

Toxicology/Drug Safety

Drug safety is one of the most important concerns throughout all stages of drug development. In the preclinical stage, drug safety needs to be studied in a variety of animals. Studies are designed to observe adverse drug effects or toxic events experienced by animals treated with different doses of the drug candidate. Animals are also exposed to the drug candidate for various lengths of time to see if there are adverse effects caused by cumulative dosing over time. These results are summarized and analyzed using statistical methods. When the results of animal studies indicate potentially serious side effects, drug development is either terminated or suspended pending further investigation of the problem.

Depending on the duration of exposure to the drug candidate, animal toxicity studies are classified as acute, subacute, chronic, or reproductive.^[4] Usually the first few studies are “acute studies”; i.e., the animal is given one or a few doses of the drug candidate. If only one dose is given, it can also be called a “single-dose study.” Only those drug candidates demonstrated to be safe in single-dose studies progress into “multiple-dose studies.” Acute studies are typically about 2 weeks in duration. Repeat-dose studies of 30–90 days’ duration are called “subacute

studies.” Chronic studies are usually designed with more than 90 days of duration. These studies are conducted in rodents and in at least one nonrodent species. Chronic studies may also be viewed as carcinogenicity studies because the rodent studies consider tumor incidence as an important endpoint. “Reproductive studies” are carried out to assess the drug's effect on fertility and conception; they can also be used to study the drug's effect on the fetus and developing offspring.

Statistical tools are very useful in designing and analyzing animal toxicity studies. Experimental design techniques are used in designing these studies; hypothesis tests are performed in comparing treatment group differences. Categorical data analysis is used to assess binary responses or count data. Life table techniques and survival analyses are very useful in analyzing chronic and carcinogenicity studies.

Drug Formulation Development

As discussed earlier, a potential new drug can be either a chemical compound or a biologic. If the drug candidate is a biologic, then the formulation is typically a solution that contains a high concentration of such a biologic, and the solution is injected into the subject. On the other hand, if the potential drug is a chemical compound, then the formulation can be tablets, capsules, solution, patches, suspension, or other forms. There are many formulation problems that require statistical analyses. The formulation problems that stem from chemical compounds are more likely to involve widely used statistical techniques, but the problems involving formulation of biologics are less likely to succumb to standard statistical solutions. The paradigm of a chemical compound is used here to illustrate some of these formulation-related problems and how statistical tools can be useful.

A drug is the mixture of the synthesized chemical compounds (active ingredients) with other, inactive ingredients designed to improve the absorption of the active ingredients. How the mixture is made depends on the results of a series of experiments, called optimization experiments. Usually the optimization experiments are performed under some physical constraints, e.g., the amount of raw materials, the capacity of the container, and the size and shape of the tablets. Some of the samples from the batch-processed tablets are stored to study the stability, or shelf life. These stored samples are exposed to various environmental conditions, e.g., freezing, extra sunlight, very dry or very humid conditions. Part of these stored samples are reanalyzed after half a year, 1 year, and 2 or more years. Such sample properties as potency, dissolution rate, and color, are measured at these time points to study the stability of the drug.

A few branches of statistics can be helpful in designing and analyzing these experiments. Optimization designs, factorial designs, or fractional factorial designs can be used

in designing these experiments. After the experiments are over and data are collected, statistical tools are used to analyze these data. Variable selection techniques of multiple regression help select the best subset of independent variables. Analysis of variance (ANOVA) is used to perform data analysis and to test various statistical hypotheses. In cases where multiple dependent variables are to be optimized, multivariate analysis (including MANOVA) may be used to analyze these data. Response surface methodology provides ways to estimate the optimal combination of a set of independent variables. From these results, pharmacists are able to operate under the physical constraints and to select the appropriate materials and processes to produce the tablets for a compound so that the tablets possess some optimal properties.

PREMARKETING CLINICAL DEVELOPMENT

If a compound or a biologic passes the selection process from animal testing and is shown to be safe and efficacious to be tested in human, it progresses into clinical development. As discussed earlier, the major distinction between clinical trials and nonclinical testing is the experimental unit. In clinical trials, the experimental units are human beings, whereas the experimental units in nonclinical testing are nonhuman subjects. Before a drug candidate can be tested in humans, the pharmaceutical company (sponsor) has to submit an IND to the FDA for review. If there is no response from the FDA after 30 days following IND submission, the sponsor can start clinical testing for this drug candidate. This compound or biologic may be referred to as the “new drug.”

An IND is a document that contains all the information known about the new drug up to the time the IND is prepared. Generally, the IND includes the name and description of the drug (chemical structure, other ingredients, etc.); how the drug is processed, manufactured, and packaged; information about any preclinical experiences relating to the safety of the drug; marketing information; past experiences or future plans for investigating the drug in foreign countries. In addition, it also contains a description of the clinical development plan. Such a description should contain all of the informational materials supplied to clinical investigators, the educational and scientific background of these investigators, a signed agreement from the investigators, and the initial protocols for clinical investigation.

Clinical development is broadly divided into four phases, namely, phases 1, 2, 3, and 4. Phase 1 trials are designed to study short-term effects of the new drug, e.g., dose range (What range of doses should be tested in humans?), pharmacokinetics (PK; What does a human body do to the drug?), and pharmacodynamics (PD; What does a drug do to the human body?). Phase 2 trials are designed to study the efficacy of the new drug in well-defined subject populations. Dose–response relationships are also studied during

phase 2. Phase 3 studies are usually long-term, large-scale studies to confirm findings established from earlier trials. These studies are also used to detect toxic effects caused by cumulative dosing. If a new drug is found to be safe and efficacious during the first three phases of clinical testing, an NDA is filed for regulatory agencies to review (e.g., FDA, in the United States). Note that for marketing approval of a new drug product, the U.S. FDA requires that substantial evidence of the effectiveness of the drug product be provided through the conduct of at least two adequate and well-controlled clinical trials. However, under certain circumstances, the U.S. FDA Modernization Act of 1997 includes a provision to allow data from one adequate and well-controlled clinical trial investigation and confirmatory evidence to establish effectiveness for risk/benefit assessment of drug and biological candidates for approval.^[5] Once the drug is approved by the FDA, phase 4 (postmarketing) studies are planned and carried out. Many of the phase 4 study designs are dictated by the FDA to examine safety questions; some are used to establish new uses. The following sections discuss “Phase 1 Clinical Trials,” “Phase 2/3 Clinical Trials,” and “New Drug Application.”

Phase 1 Clinical Trials

In a Phase 1 pharmacokinetics (PK) study, the purpose is usually to study the bioavailability of a drug or the bioequivalence among different formulations of the same drug. Bioavailability means “the rate and extent to which the active drug ingredient or therapeutic moiety is absorbed and becomes available at the site of drug action.”^[6] Experimental units in Phase 1 studies are mostly normal volunteers. Subjects recruited for these studies are generally in good health.

A bioavailability or bioequivalence study is carried out by measuring drug concentration in human blood or serum over time and then analyzing summary data from these measurements. Fig. 2 presents a drug concentration–time curve; data on this curve are collected at discrete time points. Typical variables used for analysis of PK activities

Fig. 2 Drug concentration in blood samples collected over time

include area under the curve (AUC), maximum concentration ($C_{\max}$), time to maximum concentration ($T_{\max}$), among others. These variables are computed from drug concentration levels, as shown in Fig. 2. Suppose AUC is the variable to be analyzed, then these discretely observed points are connected (for each subject) and the area under the curve is estimated using a trapezoidal rule. For example, AUC up to 24 hr for this curve is computed by adding up the area of the triangle between hour 0 and hour 0.25, the area of the trapezoid between hour 0.25 and hour 0.5, and so on through the area of the triangle between hour 16 and hour 24.

Statistical designs used in phase 1 bioavailability studies are often crossover designs; that is, a subject is randomized to be treated with drug A first and then treated with drug B after a “washout” period, or randomized to drug B first and then treated with drug A. In some complicated phase 1 studies, two or more treatments may be designed to cross several periods for each subject. The advantages and disadvantages of crossover designs are discussed in Chow and Liu.^[6] Response variables, including AUC, $T_{\max}$, and $C_{\max}$, are usually analyzed using ANOVA models. Random-effects and mixed-effects linear/nonlinear models are also commonly used in the analysis of Phase 1 clinical studies. In certain designs, model terms considered in these models can be very complicated.

Phase 2/3 Clinical Trials

Phase 2/3 trials are designed to study the efficacy and safety of a test drug. Unlike phase 1 studies, subjects recruited in Phase 2/3 studies are patients with the disease that the drug is developed for. Response variables considered in phase 2/3 studies are mainly efficacy variables and safety variables. For example, in a trial for the evaluation of hypertension (high blood pressure), the efficacy variables are blood pressure measurements. For an anti-infective trial, the response variables can be the number of subjects cured or the time to cure for each subject. Phase 2/3 studies are designed mostly with parallel treatment groups; i.e., if a patient is randomized to receive treatment A, then this patient would be treated with drug A throughout the whole study.

Phase 2 trials are often designed to compare a test drug against placebo. These studies are usually short term (a few weeks) and designed with a small or moderate sample size. Often, phase 2 trials are exploratory trials. One very important type of phase 2 study is the dose–response study. As in the left curve of Fig. 1, drug efficacy may increase as dose increases. In a dose–response study, the following fundamental questions need to be addressed:^[7]

Is there any evidence of a drug effect?

What doses exhibit a response different from the control response?

What is the nature of the dose–response relationship?

What is the optimal dose?

Typical dose–response studies are designed with fixed-dose, parallel treatment groups. For example, in a four-treatment group trial designed to study dose–response relationships, three test doses—low, medium, and high—are compared against a placebo. In this case, results may be analyzed using multiple comparison techniques.

Phase 3 trials are long term (can be a few years) and large scale, with less restricted patient populations, and often compared against a known active drug for the disease to be studied. Phase 3 trials tend to be confirmatory trials designed to verify findings established from early studies.

Statistical methods used in phase 2/3 clinical studies can be very different. Statistical analyses are selected based on the distribution of the variables and the objectives of the study. Categorical data analyses are frequently used in analyzing count data (e.g., number of subjects who responded, number with side effects, or number of subjects improved from “severe symptom” to “mild symptom”). Survival analyses are commonly used in analyzing time to an event (such as time to discontinuation of the study medication, time to the first occurrence of a side effect, or time to cure). *T* tests, regression analyses, analyses of variance (ANOVA), analyses of covariance (ANCOVA), and multivariate analyses (MANOVA) are useful in analyzing continuous data (e.g., blood pressure, grip strength, forced expiration volume, number of painful joints, area under the curve). In many cases, nonparametric analytical methods are selected because the data do not fit any known parametric distribution well. In other cases, the raw data are transformed (log-transformed, ranked, centralized, combined) before a statistical analysis is performed. A combination of various statistical tools may sometimes be used in a drug-development program. Hypotheses tests are often used to compare results obtained from different treatment groups. Point estimates and interval estimates are also frequently used to estimate subject responses to a study medication or to demonstrate equivalence between two treatment groups.

After a clinical study is completed, all of the data collected from the study are to be stored in a database; statistical analyses are performed on data sets generated from the database. A study report is prepared for each completed clinical trial. It is a joint effort to prepare such a study report. Statisticians, data managers, and programmers work together to produce tables, figures, and statistical report. Clinicians and technical writers will then put together clinical interpretations of these results. All of these are incorporated into a study report. Study reports from individual clinical trials are eventually put together as part of an NDA.

New Drug Application

When there is sufficient evidence to demonstrate a new drug that works and is safe, a new drug application is put together by the sponsor. An NDA is a huge document describing all of the results obtained from both nonclinical experiments and clinical trials. A typical NDA contains

sections on proposed drug labeling, pharmacological class, foreign marketing history, chemistry, manufacturing and controls, nonclinical pharmacology and toxicology summary, human pharmacokinetics and bioavailability summary, microbiology summary, clinical data summary, results of statistical analyses, benefit/risk relationship, and so on. If the sponsor intends to market the new drug in other countries, then separate packages will need to be prepared for submission to each corresponding country, too. For example, a new drug submission (NDS) needs to be filed with Canada's regulatory agency, a marketing authorization application (MAA) needs to be filed with the U.K. regulatory agency.

Oftentimes an NDA is filed while the phase 3 studies are ongoing. Sponsors need to be very careful in selecting the data cutoff date, because all of the clinical data in the database up to the cutoff date need to be frozen and stored so that NDA study report tables and figures can be produced from them. The data sets stored in such an NDA database may have to be retrieved and reanalyzed after filing in order to address various queries from regulatory agencies. After these data sets are created and stored, ongoing clinical data can then be entered into the regular database.

An NDA package usually includes not only individual clinical study reports, but also combined study results. These results may be summarized using meta-analyses or pooled-data analyses. Such analyses are performed on efficacy data to produce the "integrated summary of efficacy" and on safety data to produce the "integrated summary of safety." These summaries are important components of any NDA. In some cases, electronic submissions are filed as part of the NDA. Electronic submissions usually include individual clinical data, programs to process these data, and software/hardware to help FDA reviewers review the individual data as well as the whole NDA package.

POSTMARKETING CLINICAL DEVELOPMENT

An NDA serves as a landmark of the drug-development process. The development process does not stop when an NDA is submitted or approved. But the objectives of the process are changed after the drug is approved and is available on the market. Studies performed after the drug is approved are typically called postmarketing studies or phase 4 studies.

One of the major objectives in postmarketing development is to establish a better safety profile for the new drug. Large-scale, drug-safety surveillance studies are very common in phase 4. Subjects/patients recruited in phases 1, 2, and 3 are typically somewhat restricted (patients would have to be within a certain age range, gender, disease

severity, etc.). However, after the new drug is approved and is available to the general patient population, every patient with the indicated disease can be exposed to this drug. Problems related to drug safety that have not been detected from the premarketing studies (phases 1, 2, and 3) may now be observed in this large, general population.

Finally, another type of study frequently found in the postmarketing stage is to use the new drug for additional indications (symptoms or diseases). A drug developed for disease A may also be useful for disease B, but the sponsor may not have sufficient resources (budget, manpower) to develop the drug for both indications at the same time. In this case, the sponsor may decide first to develop the drug for disease A and obtain approval for the drug to be on the market and then to develop it for disease B. Phase 4 studies designed for "new indications" are also very common.

CONCLUSION

In the process of discovering and developing new drugs, much scientific work is involved. Potential drug candidates progress from preclinical experiments to clinical trials. During the clinical development process, drugs are tested at phases 1, 2, and 3 before they are submitted to the FDA. They are then further tested at phase 4 after approval for marketing. This is a large-scale, time-consuming, and expensive process in which a large number of scientists with various training and experiences is involved. This is why it takes substantial investments and a long time to discover and develop new drugs.

Abstract

When the patent of a biological drug expires, alternative, biosimilar products are often developed. They are expected to have highly similar clinical effects with the original drug. Still, even after the approval of the biosimilarity of two drug products, their interchangeability within subjects remains to be determined. Regulatory authorities in the United States, Canada and the European Union follow differing approaches to the approval of interchangeability. The disbursement of funds for drugs and, consequently, the decisions for interchangeability are generally left for the states, provinces and constituent states. This leads to widely diverging practices and, in the United States, possible legal complications. Statistical approaches are presented for the determination of the switching, alternation and interchangeability of biological products and for the design of the corresponding studies.

Keywords: Biosimilarity; Interchangeability; Switching; Alternation; Regulatory approaches; Statistical evaluation.

INTRODUCTION

Following the expiry of the patent of an innovative biological drug, alternative, biosimilar products are often developed. Biological drugs are therapeutic agents which are produced using a living system or organism. However, the size and complexity of biological molecules are much larger, their manufacturing processes are more complicated and difficult than those of chemistry-based drugs, and they may exhibit immunogenicity (unwanted immune response when the immune system recognizes a large molecule as a foreign invader). Consequently, an alternative biological product cannot be identical but only similar (i.e., biosimilar) to the drug of an originator. The two products should be highly similar so that their clinical effects should also be very close. The issue of what is “highly similar” is a matter of judgment and is based on the totality-of-the-evidence.^[1] This involves several considerations including structural, functional, analytical, immunological, pharmacokinetic, pharmacodynamics, manufacturing and clinical similarities.

Even if two products are judged and declared to be biosimilar, their interchangeability requires much more convincing evidence which can be obtained only from additional investigations and calls for further, careful judgment. For example, the Biologics Price Competition and Innovation (BPCI) Act of the United States sets

biosimilarity as a precondition for interchangeability and imposes additional requirements.^[2] These will be discussed later.

Thus, at least in the United States, approved biosimilar preparations may, without further permission, not be switched from and to their reference drug. There is a clear separation between their *prescribability* and *switchability*. Anderson and Hauck^[3] actually distinguished between these two terms even for small-molecule generic products. Two situations can be considered.

In the first situation, a patient had no prior exposure to a drug in any of its forms, i.e., s/he has been naïve to the drug. Under such conditions, any of the approved formulations are *prescribable* provided that their safety and efficacy are acceptable and, therefore, they have been approved by regulators. However, after the patient has started to receive one of the formulations, it may not be substituted by another product.

In the second situation, the patient is already taking the drug but opts for a cheaper alternative for economic reasons. In this case, the different products must be therapeutically closely similar. Therefore, the products will be *switchable* within individuals. The switch usually occurs from the reference drug to the test drug, which is denoted by “R → T”.

Switching between marketed drug products can become more general, and they can be entirely *interchangeable*.

Directions of *switches* are possible like the T→R and T→T' switch; here T' is a second biosimilar test product. Consequently, a more general *alternation* can be envisaged between the various biosimilar products as well as with the original drug. The products R, T and T' must be interchangeable in any possible sense to achieve a closely similar therapeutic effect after a switch and alternation.

Practices of and issues on the interchangeability of biological products in the United States, Canada and Europe will be described. Statistical approaches will then be presented. A few remarks will conclude this entry.

INTERCHANGEABILITY OF BIOSIMILARS

General Questions and Concerns

Klein et al.^[4] noted several questions for the careful consideration of substitution and interchangeability between biological products. They observed that the “complexity and impurity profile of an SEB means that automatic interchangeability of SEBs, or even of originator biologicals, has a real potential for different, and sometimes unexpected, clinical consequences”.

Another possible concern is that switching between biological products can exacerbate immunogenicity, with potentially negative effects. Klein et al.^[4] note that the immunogenicity of biosimilars “cannot be fully predicted using preclinical/clinical studies as the process is abbreviated and the number of patients/subjects in clinical studies is relatively limited.” For example, loss of tolerance and loss of efficacy was observed within 1 year when patients, having Crohn's disease and maintained with infliximab, were switched to adalimumab as compared to patients who remained on infliximab therapy.^[5]

Professional organizations raised concerns about switching patients from an effective and safe biological drug to a biosimilar. For instance, the British Society of Rheumatology^[6] advised against the summary switching of such patients. A committee of the European Society for Paediatric Gastroenterology, Hepatology, and Nutrition recommended that children with inflammatory bowel disease not be switched at present to a biosimilar.^[7]

Another concern is that the various responses of the biosimilar and also of the reference drug could drift in time.^[8] They form the basis of the totality-of-the-evidence for the judgment on biosimilarity. As a document of Health Canada observes, over time the biosimilar and reference products “make their own independent manufacturing changes, differences could be introduced that affect the drug products”.^[9]

United States

The Biologics Price Competition and Innovation (BPCI) Act of 2009 in the United States, clearly defines, separately, both biosimilarity and interchangeability.^[2]

The BPCI Act defines the term biosimilar (or biosimilarity) as when the biological product is *highly similar* to the reference product (notwithstanding minor differences in clinically inactive components), and also when there are *no clinically meaningful differences* between the biosimilar product and the reference product in terms of safety, purity and potency.

The BPCI Act of the United States provides explicit definitions and conditions for interchangeability. “The terms *interchangeable* and *interchangeability* mean that: (1) the biological product is *biosimilar* to the reference product; (2) the biological product can be *expected* to produce the *same clinical result* as the reference product *in any given patient*; (3) for a product administered more than once, the *risks of safety and reduced efficacy of alternating and switching* are not greater than with the use of the reference product without alternating or switching.” (Emphasis has been added.)

There is a clear and strong distinction between *biosimilarity* and *interchangeability*. Biosimilarity is a precondition of interchangeability. The regulatory approval of the biosimilarity of two products does not imply at all their interchangeability. If two biological products have already been approved and are marketed, an additional application must be submitted which would demonstrate that conditions for their interchangeability are also satisfied.

The strong distinction and hierarchy between the biosimilarity and interchangeability of biological products is in sharp contrast to the close parallel between the bioequivalence and interchangeability of small-molecule drug products.

However, while the BPCI Act distinguishes between biosimilarity and interchangeability, such a distinction is still to be seen in the forthcoming FDA guidelines. This has already led to legal controversies.

FDA published in January, 2017 a draft guidance on the interchangeability.^[10] It defines switching and alternating as changes occurring between the biosimilar and reference products. It describes a dedicated switching study design in which a lead-in period of treatment with the reference product is followed by a randomized two-arm period. One arm incorporates switchings between the proposed interchangeable product and the reference product whereas subjects in the other arm continue to receive the reference drug. An integrated study design could assess both the high similarity of the two drug products and their interchangeability.

FDA strongly recommends that patients be used in switching studies. If a sponsor intends to involve healthy subjects, the possible risks should be discussed with the agency. FDA strongly recommends also that U.S.-licensed reference products be used in switching studies.

Automatic Substitution in the United States

The BPCI Act of the United States decrees also important consequences for the approval of interchangeability

between biological drug products. The BPCI Act states that the interchangeable “biological product may be substituted for the reference product without the intervention of the health care provider who prescribed the reference product”.^[12]

Consequently, according to the BPCI Act, if a test product is judged to be interchangeable with the reference product then it may be substituted, even alternated, without a possible intervention, or even notification, of the prescribing physician.

This is a very permissive stipulation and has raised concerns at the level of state legislations. The basis of these concerns is that substitution of a drug product by another could give rise to changes of the safety and efficacy in individuals. It is assumed, however, that risks associated with these changes are well controlled.

For instance, when a patient is switched from a reference formulation to a test product, $R \rightarrow T$, then the associated risk should not be higher than when the subject is exposed to the reference product twice: $R \rightarrow R'$. This was the sense of the earlier considerations of individual bioequivalence.

Scenarios of switching and alternating have not been stated yet by the FDA. On the other hand, as of January 4, 2016, at least 31 states have considered legislation establishing state standard for substitution of biosimilar prescription product to replace the original biological product.^[11] It was signed into law in 18 states and Puerto Rico.

The language of the legislations can be confusing. They generally refer to the substitution of a prescribed biological product by an alternative biological product, as in California. This may mean alternative prescription but may imply also interchanging. It is therefore reassuring that the legislations generally contain various safeguards and conditions.^[11] For example, they often refer to the need of approval of interchangeability by FDA. Some require that the prescriber and/or the patient be notified. The prescriber's active or passive (“does not object”) approval of substitution is generally sought. Some provide liability protections for pharmacists who substitute biosimilars.

However, there is pressure to extend automatic substitution. For example, the Generic Pharmaceutical Association stated in 2015: “The Generic Pharmaceutical Association (GPhA) and its Biosimilars Council applaud the enactment of legislation in five states to allow automatic substitution for Food and Drug Administration (FDA) approved interchangeable biologic products.”^[12] The statement appears to reach somewhat beyond the intent and content of the legislations: interchangeability is not automatic but subject to conditions and constraints.

The conditions and constraints of the state legislations are more cautious (for instance, when they refer to the approval of substitution by the prescriber) than the federal BPCI Act which, as seen above, calls for substitution by biosimilars without the intervention of the prescriber. The differing views may require legal resolution.

Canada

In Canada, the term “substitutability” is applied to two products which can both be used in lieu of the other during and within the same treatment period, i.e. for interchangeability as discussed in this paper. The general guidance of Health Canada on biosimilars does not consider interchangeability.^[13] Still, the position of Health Canada on the substitution of biological products is clear but rather soft: “Health Canada does not support the automatic substitution of a subsequent-entry biologic for its reference biologic drug. Health Canada therefore recommends that physicians make only well-informed decisions regarding therapeutic interchange”.^[9]

The position of Health Canada does not have legal authority. Funds for the reimbursement of pharmaceutical expenses are dispensed by the provinces. They will be keen to promote introduction of new biosimilar products, i.e. their prescribability. The interchangeability of biologic products, and the related conditions, will be diverse and controversial.

European Union

The EU was the first region in the world to have set up legal framework and regulatory pathways for biosimilars. In fact, the word “biosimilars” was coined during this legislative process.

The concept of a “similar biological medicinal product” was adopted in EU pharmaceutical legislation in 2004 and came into effect in 2005. The EMA was the first to lay down an abbreviated regulatory pathway for biosimilars. As of April 2016, 23 biosimilars were approved within the product classes of human growth hormone, granulocyte colony-stimulating factor, erythropoietin, follitropin, TNF-inhibitor and insulin for use in the EU; some products were withdrawn.^[14] The European Medicines Agency has issued many guidelines for biosimilars, including several product-class specific guidelines. A general guideline on biosimilars was issued in 2014.^[15]

Only EMA can grant marketing authorization for biosimilars in the European Union. More precisely, the European Commission issues the decisions concerning the authorization of these medicinal products on the basis of the scientific opinions from the EMA. The resulting marketing authorization is valid in all EU Member States.

For granting approval for a biosimilar product, EMA generally requires clinical trials, including comparability studies to the originator product, to demonstrate safety and efficacy. Unlike generics, demonstration of bioequivalence is not enough for biosimilars. Additionally, the prospective market authorization holder also must demonstrate lack or at least comparable immunogenicity in long-term clinical trials. Guidelines were established to provide further details on specific needs for demonstrating biosimilarity for nine primary product classes.^[16]

The EMA has made it clear that a biosimilar is not the same as a generic drug and handed the interchangeability issue over to individual countries. As an EMA document states:^[17] “The EMA evaluates biosimilar medicines for authorization purposes. The Agency’s evaluations do not include recommendations on whether a biosimilar should be used interchangeably with its reference medicine. For questions related to switching from one biological medicine to another, patients should speak to their doctor or pharmacist.”

In the absence of central European directives, the 28 member states follow diverse directions. In several countries, either legislation has been passed or regulations prohibit automatic substitution by pharmacists.^[17] Given that most currently approved biosimilars are applicable only in hospital settings, the impact of such a strict prohibition is moderate. At the other extreme, some countries (e.g., Poland and Bulgaria) have no relevant law or guidelines and permit automatic substitution. Substitution is conditional in several other countries.^[18]

Equally important is the reimbursement policy^[19] where there are many national variations. One of the options is that new patients need to be treated with a biosimilar product if it is available, otherwise the treatment is not reimbursed. But patients already treated with a brand-name biological have the right to continue receiving the same biological brand. Consequently, the prescribability but not the interchangeability of biosimilar products is recommended.

There has been considerable experience in Europe with switching. No evidence has been found from either clinical trials or post-marketing surveillance that switching to and from different biopharmaceuticals, including biosimilar medicines, leads to safety concerns.^[20]

To describe the different scenarios, a European Consensus Group on Biosimilars proposed to make distinction between interchangeability, switching and substitution. According to the consensus document:^[21]

- Interchangeability means changing one medicine with the agreement of the prescriber.
- Switching means a decision by the treating physician to exchange one medicine for another.
- Substitution means of the practice of dispensing one medicine instead of another equivalent and interchangeable medicine at the pharmacy level without consulting the prescriber.

Making such distinctions between the post-approval use of biosimilars may be needed to describe the different possibilities. But reloading the meaning of these common English words which in some countries have been used as synonyms, could lead to confusion. The word switching appears to be a particularly bad choice of wording because some English speakers seem to associate switching with the inadvertent exchange of medicines. Moreover, confusion could arise, and has arisen, because the terms could be interpreted for the conditions of both prescribability (between subjects) and switch ability (within subjects).^[22]

STATISTICAL CONSIDERATIONS ON THE INTERCHANGEABILITY OF BIOLOGICAL PRODUCTS

A Possible Resolution of the Problematic Definition of Interchangeability

The definitions of the American BPCI Act for the interchangeability of biologicals were outlined earlier. One of them is particularly forbidding, apparently categorical: “the biological product can be *expected* to produce the *same* clinical result as the reference product in *any* given patient”. Responses of patients are variable and the same clinical response may not be anticipated. Furthermore, the expectation of the *same* result in *any* given patient could be interpreted to mean that if an individual experiences an unexpected (not to say, not the “same”) therapeutic or adverse effect s/he may well seek recourse. Lawyers, notably in the United States, would undoubtedly encourage this.

However, the word “*expected*” in the above phrase could be interpreted that the “same clinical result ... in any given patient” is not a categorical rule but only an expectation. “Expectation” has also a probabilistic meaning which involves some stated statistical assurance. It is hoped that this interpretation will be duly considered and adopted.

Study Designs for Interchangeability

While many biologicals have long terminal half-lives, some don’t. With these, it is possible to contemplate cross-over investigations which would enable the assessment of features of interchangeability. Notably, switching between two biological products, either reference (R) or test (T), such as R→T, T→R, R→R’, T→T’, could be investigated by Balaam’s 4 × 2 crossover design with 4 sequences and 2 periods,^[23,24] including the sequences of RT, TR, RR’, TT’. Here, e.g., RT refers to a sequence in which first the reference and then, after a sufficient washout period, the test product is provided to each individual. R and R’ denote two administrations of the reference product. Similarly, alternating between the test and reference products, i.e., R→T→R’, T→R→T’, could be studied by a 2-sequence, 3-period design with the sequences of RTR’, TRT’. Finally, both switching and alternating could be investigated by modifying Balaam’s design in 4 sequences and either 2 or 3 periods: TT’, RR’, TRT’, RTR’.

Statistical Assessment of Switching and Alternation

Assessment of Biosimilarity

In order to quantify switching and alternating and to provide statistical measures for their evaluation, Chow^[25] developed relevant measures. First, however, indices are considered for the quantitative assessment of biosimilarity.

For a given criterion of biosimilarity and under a valid study design, a *local biosimilarity index* can be obtained for a given functional area or domain by the following steps:^[26]

- Step 1: Assess average biosimilarity based on a given criterion, e.g. (80%, 125%) based on log-transformed data;
- Step 2: Calculate the *local biosimilarity index* (i.e., reproducibility) based on the observed ratio and variability;
- Step 3: Claim *local biosimilarity* if the 95% confidence lower bound of p is larger than p_0 , a pre-specified number, where p_0 can be obtained based on an estimated of reproducibility probability for a study comparing a reference product to itself (the reference product), i.e., an R-R study.

A *totality biosimilarity index* can be derived across all functional areas or domains can be obtained by the following steps:

- Step 1: Obtain $\hat{p}_i$, the biosimilarity index for the i -th domain;
- Step 2: Define the *totality biosimilarity index* as $\hat{p}_T = \sum_{i=1}^n w_i \hat{p}_i$ where w_i is the weight for the i -th domain, where $i = 1, 2, \dots, K$ (the number of domains or functional areas);
- Step 3: Claim biosimilarity if the 95% confidence lower bound of p_T is larger than a pre-specified value p_0 , which can be determined based on an estimated of *totality biosimilarity index* for studies comparing a reference product to itself (the reference product).

This *totality biosimilarity index* has the advantages that (1) it is robust with respect to the selected study endpoint, biosimilarity criteria, and study design, (2) it takes variability into consideration (one of the major criticisms in the assessment of average bioequivalence), (3) it allows the definition and assessment the degree of similarity (in other words, it provides partial answer to the question that “how similar is considered similar?”), and (4) the use of the biosimilarity index or totality biosimilarity index will reflect the sensitivity of heterogeneity in variance.

Assessment of Switching and Alternation

A similar idea can be applied to develop a *switching index* under an appropriate study design such as the crossover 4×2 Balaam design.^[27] Thus, the issue of switching needs to be addressed for the switches of $R \rightarrow T$, $T \rightarrow R$, $T \rightarrow T'$ and $R \rightarrow R'$.

Define $\hat{p}_T$ the totality biosimilarity index for the i -th switch, where $i = 1$ (the $R \rightarrow R'$ switch), 2 (for $T \rightarrow T'$), 3

(for $R \rightarrow T$), and 4 (for $T \rightarrow R$). As a result, a *switching index* (SI) can be calculated as follows:

- Step 1: Obtain $\hat{p}_T$; $i = 1, \dots, 4$;
- Step 2: Define the switching index as $SI = \max_i \{\hat{p}_T\}$, $i = 1, \dots, 4$, which is the largest order of the biosimilarity indices;
- Step 3: Claim switchability if the 95% confidence lower bound of p_s , $i = 1, \dots, 4$, is larger than a pre-specified value.

An *alternating index* can be developed similarly under an appropriate study design. Under the modified crossover Balaam design of (TT, RR, TRT, RTR), alternation can be evaluated with the $R \rightarrow T \rightarrow R$ and $T \rightarrow R \rightarrow T$ designs. For example, the assessment of differences between the switches of $R \rightarrow T$ and $T \rightarrow R'$ for the alternating of $R \rightarrow T \rightarrow R$ needs to be evaluated in order to determine whether the drug effect has returned to the baseline after the second switch. The *alternating index* can be calculated as follows:

Define p_{Ti} as the totality biosimilarity index for the i -th switch, where $i = 1$ refers to the switch $R \rightarrow R'$, $i = 2$ to the switch $T \rightarrow T'$, 3 to $R \rightarrow T$, and 4 to $T \rightarrow R$. As a result, the *alternating index* (AI) can be calculated as follows:

- Step 1: Obtain $\hat{p}_{Ti}$, $i = 1, \dots, 4$;
- Step 2: Define the range of these indexes, $AI = \max_i \{\hat{p}_{Ti}\} - \min_i \{\hat{p}_{Ti}\}$, $i = 1, \dots, 4$, as the alternating index;
- Step 3: Claim alternation if the 95% confidence lower bound of $\max_i \{p_{Ti}\} - \min_i \{p_{Ti}\}$, $i = 1, \dots, 4$, is larger than a pre-specified value p_{A0} .

Scaled Criterion for Drug Interchangeability (SCDI)

A scaled criterion proposed for drug interchangeability is based on the model for individual bioequivalence^[28]. Its features, as described below, include (i) the criterion for average bioequivalence adjusted for the within-subject variability of the reference product, and (ii) a correction for the variability due to subject-by-product variability (i.e. σ_D^2). The proposed criterion for assessing interchangeability (i.e., switching and alternating) is briefly derived below.

The model for average BE expects that the confidence interval around the difference between the logarithmic means of the test and reference products (μ_T and μ_R , respectively) should be between the upper and lower confidence limits ($-\theta$ and θ):

$$-\theta \leq \mu_T - \mu_R \leq \theta \quad (1)$$

The model for individual bioequivalence (IBE) was implemented in the statistical guidance of FDA^[29]. The model contrasts not only the squared deviation between the two logarithmic means, $\delta^2 = (\mu_T - \mu_R)^2$, but also the

difference between the corresponding within-subject variances, $(O_{WT}^2 - O_{WR}^2)$. It contains also an additional term for the variance component of the subject-by-formulation interaction, O_D^2 :

$$\theta_1 = (\delta^2 + O_{WT}^2 - O_{WR}^2 + O_D^2) / \max\{O_{W0}^2, O_{WR}^2\} \quad (2)$$

Here O_{W0}^2 is a constant the magnitude of which is set by regulators. IBE can be claimed if the one-sided 95% upper confidence bound for θ_1 is less than a pre-specified bioequivalence limit.

For the evaluation of SCDI, the model for average BE is first adjusted for the within-subject variability:

$$-\theta' \leq \frac{\mu_T - \mu_R}{\sigma_W} \leq \theta', \quad (3a)$$

or

$$-\theta' \sigma_W \leq \mu_T - \mu_R \leq \theta' \sigma_W, \quad (3b)$$

where σ_W^2 is a within-subject variation and θ' is the limit for scaled bioequivalence. In practice, σ_{WR}^2 , the within-subject variation of the reference product is often considered.

Scaled average bioequivalence (SABE) has been applied for the assessment of BE between highly variable drug products.^[30,31]

Next consider the first two components of the individual bioequivalence model (Eq. 2):

$$\frac{(\mu_T - \mu_R)^2 + \sigma_D^2}{\sigma_W^2} = \frac{2\delta\sigma_D + (\delta - \sigma_D)^2}{\sigma_W^2} \quad (4)$$

where $\delta = \mu_T - \mu_R$. When δ and σ_D are close, we observe that

$$\frac{(\delta + \sigma_D)^2}{\sigma_W^2} \approx \frac{2\delta\sigma_D}{\sigma_W^2}. \quad (5)$$

The assumption is reasonable when both δ and σ_D are small.

Thus, the proposed scaled criterion for drug interchangeability (SCDI) is:

$$-\theta' \leq \left(\frac{\mu_T - \mu_R}{\sigma_W} \right) \frac{2\sigma_D}{\sigma_W} \leq \theta' \quad (6a)$$

Now, let $f = \sigma_W / (2\sigma_D)$, a correction factor for drug interchangeability. Then, the proposed SCDI criterion is given by:

$$-\theta' f \sigma_W \leq \mu_T - \mu_R \leq \theta' f \sigma_W \quad (6b)$$

Following the concept of the criterion for individual bioequivalence and the idea of SABE, the proposed SCDI

criterion is developed in order to adjust the usual one-size-fits-all approach for both intra-subject variability of the reference product and the variability due to subject-by-product interaction. As compared to SABE, SCDI may result in wider or narrower limits depending upon the correction factor f which is a measure of the relative magnitude between σ_{WR} and σ_D .

The proposed SCDI criterion for drug interchangeability depends upon the selection of regulatory constants for σ_{WR} and σ_D . In practice, the observed variabilities may deviate far from the regulatory constants. Thus, it is suggested that the following hypotheses be tested before the use of SCDI criterion:

$$H_{01} : \sigma_{WR} > \sigma_{W0} \quad \text{vs.} \quad H_{a1} : \sigma_{WR} > \sigma_{W0}, \quad (7a)$$

and

$$H_{02} : \sigma_D > \sigma_{D0} \quad \text{vs.} \quad H_{a2} : \sigma_D > \sigma_{D0} \quad (7b)$$

If we fail to reject the null hypotheses H_{01} or H_{02} then we will stick with the suggested individual regulatory constants; otherwise estimates of σ_{WR} and/or σ_D should be used in the SCDI criterion.

However, it should be noted that statistical properties and/or the finite sample performance of SCDI with estimates of σ_{WR} and/or σ_D are not well established. Further research is needed. Preliminary analyses of statistical power and required sample size have already been conducted.^[32]

CONCLUDING REMARKS

The important concepts of prescribability and switchability should be kept in mind when pharmacokinetic features of two drug products are compared. Regulatory approval of both small-molecule generics and biological biosimilars means directly an agreement only that they are prescribable, i.e., that the drug products may be provided to naïve patient who have not taken the drug until this point in any form.

The terminology for the interchangeability of biological products has become regrettably confusing. In the United States, the BPCI Act introduced the terms of switching and alternating without providing clear interpretation. Switching presumably refers to changing between the reference and test products, R→T and T→R, primarily the former. Alternating could involve multisource products, thus also a change of T→T'. However, a recent interpretation limited alternation to between switches between the biosimilar and reference drug products.^[10] Interchangeability would cover both switching and alternating. All these changes are conducted within subjects. It is important to emphasize this because the terms are used at times, in the literature and regulations of the states, incorrectly, when they

imply changes between subjects, i.e., when they refer to the condition of prescribability.

The situation is different, but not less confusing in the European Union. The intent of the proposed terms of switching, interchanging and substitution may be that they be considered as changes within patients.^[21] However, they are often used and implemented for changes between subjects, i.e. again in the sense of prescribability.

The European Medicines Agency has issued product-related guidelines for biosimilars, as well as a general guideline in 2014, and approved a large number of biosimilars. In some cases, these were multisource products referring to the same reference drug. No safety issues were noted following interchanging among them.^[20]

However, EMA left the decision on interchanging to member states. In some member states, prescribability and switchability are governed by the rules of health insurance policy and not by formal law. As a consequence, the regulations have spanned a wide range from those enabling automatic substitution to laws forbidding automatic substitution.^[18] This is a very regrettable situation.

FDA has followed a more cautious approach. Relying on the BPCI Act, it has issued general guidelines on various aspects on the development and regulation of biosimilars. The consideration of interchangeability requires additional demonstration; the conditions for these have not been clarified yet. FDA approved the first product (Zarxio) in March, 2016 for which the condition of interchangeability was not requested and not granted.

A situation could arise in the United States where there will be a number of biosimilar products which have been shown to be biosimilar to the same innovative (reference) drug product. It is almost impossible for a sponsor to claim or demonstrate interchangeability according to the definition as given in the BPCI Act. Alternatively, it is possible that a meta-analysis that combines all data given in the submissions be conducted (by the regulatory agency) to evaluate the relative risks of switching and alternating of drug interchangeability. In practice, meta-analysis can be conducted for safety monitoring of approved biosimilar products. This is extremely important especially when there are a number of biosimilar products in the marketplace.

Abstract

Current regulation for generic approval is based on the assessment of average bioequivalence. As indicated by the United States Food and Drug Administration (FDA), an approved generic drug can be used as a substitute for the innovative drug. The FDA does not indicate that two generic copies of the same innovative drug can be used interchangeably even though they are bioequivalent to the same brand-name drug. In practice, bioequivalence between generic copies of an innovative drug is not required. However, as more generic drug products become available, it is a concern whether the approved generic drug products have the same quality and therapeutic effect as the brand-name drug product and whether they can be used safely and interchangeably. In this article, several criteria including a newly proposed criterion for assessing drug interchangeability are studied. In addition, comments on possible study designs and power calculation for sample size under a specific design are also discussed.

Keywords: Biosimilars; Generic drugs; Individual bioequivalence; Population bioequivalence; Scaled average bioequivalence; Scaled criterion for drug interchangeability.

INTRODUCTION

In the United States, when a drug product is going off-patent, a generic company can file an abbreviated new drug application (ANDA) for generic approval. For approval of a generic drug, the Food and Drug Administration (FDA) requires that evidence of average bioequivalence in drug absorption be provided through the conduct of a bioequivalence study on healthy volunteers. As indicated by the FDA, an approved generic (test) drug of an innovative (reference) drug can serve as a substitute for the reference product. The FDA, however, did not indicate that the approved generic drug and the innovative drug can be used interchangeably.

As indicated earlier, when a generic drug is claimed bioequivalent to an innovative drug product, it is assumed that they are therapeutically equivalent. A generic drug can be used as a substitute for the innovative drug if it has been shown to be bioequivalent to the innovative drug. The FDA does not indicate that two generic copies of the same brand-name drug can be used interchangeably even though they are bioequivalent to the same brand-name drug. In practice, bioequivalence between generic copies of a brand-name drug is not required. However, as more generic drug products become available, it is a concern whether the approved generic drug products have the same quality

and therapeutic effect as the brand-name drug product and whether they can be used safely and interchangeably.

The issue of drug interchangeability has been discussed tremendously among the regulatory agency, pharmaceutical industry, and academia since the early 1990s. Several criteria for the assessment of drug interchangeability have been proposed since then. These criteria include the criteria for population bioequivalence (PBE) and individual bioequivalence (IBE),^[1,2] the potential use of variability due to the subject-by-formulation interaction,^[2,3] and a scaled criterion for drug interchangeability (SCDI).^[5] In this entry, several criteria and study designs for drug interchangeability are discussed.^[6] Under these criteria, formulas for sample size calculation can be derived.

In Section “Drug Interchangeability,” the concept of drug interchangeability in terms of drug prescribability and drug switchability is introduced. Also included in this section are the criteria for PBE, IBE, and SCDI, and a newly proposed criterion. Section “Design for Drug Interchangeability” provides some common study designs considered for addressing drug interchangeability. Formulas derived under these criteria are given in Section “Power Analysis for Sample Size.” Some comments on the study designs for drug interchangeability are provided in Section “Concluding Remarks.”

DRUG INTERCHANGEABILITY

The concept of drug interchangeability for small-molecule drug products includes drug prescribability and drug switchability. Drug prescribability is referred to as the physician's choice for prescribing an appropriate drug for his/her patients between the brand-name drug and its generic copies. Drug switchability, on the other hand, is referred to as the switch from a drug (e.g., a brand-name drug or its generic copies) to another (e.g., a generic copy) within the same patient whose concentration of the drug has been titrated to a steady, efficacious, and safe level. In what follows, criteria for assessment of PBE for addressing drug prescribability and IBE for addressing switchability,^[1,2] a possible criterion based on the variability due to the subject-by-treatment interaction,^[3,4] an SCDI,^[5] and a newly proposed criterion for drug interchangeability are briefly introduced.

CRITERIA FOR PBE AND IBE

Population Bioequivalence

To address drug prescribability, the FDA recommends that PBE be assessed. In addition to the average of bioavailability, PBE focuses on the variability of bioavailability. The 2001 FDA guidance recommends the following criterion to be used for assessing PBE:

$$\theta_p = (\delta^2 + \sigma_{TT}^2 - \sigma_{TR}^2) / \max\{\sigma_{T0}^2, \sigma_{TR}^2\}, \quad (1)$$

where $\delta = \mu_T - \mu_R$, μ_T and μ_R are the mean responses of the test product and the reference product, respectively; $\sigma_{TT}^2, \sigma_{TR}^2$ are the total variances for the test product and the reference product, respectively; and σ_{T0}^2 is the scale parameter specified by the regulatory agency or the sponsor. PBE can be claimed if the one-sided 95% upper confidence bound for θ_p is less than a prespecified bioequivalence limit. In view of the above PBE criterion, PBE can be claimed if the null hypothesis in

$$H_0 : \lambda \geq 0 \text{ vs. } H_a : \lambda < 0$$

is rejected at the 5% level of significance and the observed geometric means ratio (GMR) is within the limits of 80% and 125%, where

$$\lambda = \delta^2 + \sigma_{TT}^2 - \sigma_{TR}^2 - \theta_p \max\{\sigma_{TR}^2, \sigma_{T0}^2\}$$

and θ_p is a constant specified in the 2001 FDA draft guidance.

Individual Bioequivalence

To address drug switchability, the FDA suggests that IBE be assessed. The 2001 FDA guidance recommends the following criterion to be used for assessing IBE:

$$\theta_l = \frac{(\mu_T - \mu_R)^2 + \sigma_D^2 + (\sigma_{WT}^2 - \sigma_{WR}^2)}{\max\{\sigma_{w0}^2, \sigma_{WR}^2\}},$$

where $\delta = \mu_T - \mu_R$, σ_D^2 is the variance component due to the subject-by-treatment interaction between drug products, and σ_{WR}^2 and σ_{WT}^2 are intra-subject variances for the reference product and the test product, respectively. Thus, we have

$$\theta_l = (\delta^2 + \sigma_D^2 + \sigma_{WT}^2 - \sigma_{WR}^2) / \max\{\sigma_{w0}^2, \sigma_{WR}^2\}, \quad (2)$$

where σ_{w0}^2 is the scale parameter specified by the regulatory agency or the sponsor. In view of the above IBE criterion, IBE can be claimed if the null hypothesis in

$$H_0 : \gamma \geq 0 \text{ vs. } H_a : \gamma < 0$$

is rejected at the 5% level of significance, and the observed GMR is within the limits of 80% and 125%, where

$$\gamma = \delta^2 + \sigma_D^2 + \sigma_{WT}^2 - \sigma_{WR}^2 - \theta_l \max\{\sigma_{WR}^2, \sigma_{w0}^2\}$$

and θ_l is a constant specified in the 2001 FDA draft guidance.

CRITERION FOR DRUG INTERCHANGEABILITY BASED ON σ_D

For addressing drug interchangeability, the FDA suggests that PBE and IBE be assessed under replicated crossover designs such as a replicated 2×2 crossover design, i.e., (TRTR, RTTR) or a 2×3 two-sequence dual design, i.e., (TRT, RTR). Under the 2×2 replicated crossover design, the one-sided 95% upper confidence bound for θ_l can be obtained under the following statistical model:

$$y_{ijk} = \mu + F_l + W_{ijk} + S_{ikl} + \epsilon_{ijk}, \quad (3)$$

where μ is the overall mean, F_l is the fixed effect of the l th drug product, W_{ijk} 's are fixed period, sequence, and interaction effects, S_{ijk} is the random effect of the i th subject in the k th sequence under the l th drug product, and ϵ_{ijk} 's are independent random errors distributed as $N(0, \sigma_{wi}^2)$. It is assumed that S_{ijk} 's and ϵ_{ijk} 's are mutually independent. Under model Eq. 3, σ_D^2 is given by

$$\sigma_D^2 = \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho\sigma_{BT}\sigma_{BR}, \quad (4)$$

which is variance of $S_{ikT} - S_{ikR}$. Note that σ_D^2 is usually referred to as the variance due to the subject-by-drug interaction.

Chen et al.^[3] indicated that IBE is to address drug switchability and variability due to the subject-by-treatment interaction is an indicator of drug switchability.

Further, Chen et al.^[3] pointed out that a value of 0.15 for the estimation of the standard deviation due to the subject-by-drug product may be considered to be important. In other words, we can test as to whether σ_D is greater than 0.15 for drug interchangeability. However, Endrenyi et al.^[4] pointed out that positive bias observed for the estimation of the variability due to the subject-by-treatment interaction—in other words, about a quarter to one-third of estimates greater than 0.15. These estimates do not result from the true existence of the subject-by-formulation interaction rather than the large intra-subject variability of the reference formulation. The results from the FDA data sets exhibit almost an identical pattern.

SCALED CRITERION FOR DRUG INTERCHANGEABILITY

While the criterion for the determination of average biosimilarity is based on the BE requirement of (80.00%, 125.00%) using log-transformed data, the criterion for the assessment of interchangeability is not clear. As indicated by Chen et al.,^[3] variability due to the subject-by-drug formulation interaction will have an impact on drug interchangeability. Let σ_D^2 be the variance component due to the subject-by-formulation interaction. We would like to propose a criterion to adjust for both intra-subject variability and the variability due to subject-by-formulation variability. The current BE criterion adjusted for intra-subject variability leads to so-called scaled average bioequivalence (SABE) criterion, which is considered suitable for highly variable drug products. In addition to adjusting intra-subject variability, following the idea of IBE, we may further adjust the BE criterion with respect to the variability due to subject-by-formulation variability in order to have a more accurate and reliable assessment of interchangeability. As indicated in the 2001 FDA guidance on bioequivalence, the criterion for assessing IBE is given in Eq. 2.

Chow et al.^[5] proposed an SCDI based on the first two components of the criterion for IBE, which consists of (i) the criterion for average biosimilarity adjusted for intra-subject variability of the reference product (i.e., SABE) and (ii) the correction for variability due to subject-by-product variability (i.e., σ_D^2). The proposed SCDI for assessing interchangeability (i.e., switching and alternating) is briefly derived as follows:

Step 1: Unscaled ABE criterion—Let BEL be the BE limit, which generally equals 1.25. Thus, biosimilarity requires that $\frac{1}{\text{BEL}} \leq \text{GMR} \leq \text{BEL}$. This implies

$$-\log(\text{BEL}) \leq \log(\text{GMR}) \leq \log(\text{BEL})$$

or

$$-\log(\text{BEL}) \leq \mu_T - \mu_R \leq \log(\text{BEL}),$$

where μ_T and μ_R are the logarithmic means.

Step 2: SABE criterion—Difference in logarithmic means is adjusted for intra-subject variability as follows:

$$-\log(\text{BELS}) \leq \frac{\mu_T - \mu_R}{\sigma_w} \leq \log(\text{BELS})$$

or

$$-\log(\text{BELS})\sigma_w \leq \mu_T - \mu_R \leq \log(\text{BELS})\sigma_w,$$

where σ_w^2 is a within-subject variation and BELS is the BE limit for SABE. In practice, σ_{wR}^2 , the within-subject variation of the reference product, is often considered.

Step 3: Proposed SCDI—Considering the first two components of the IBE criterion, we have the following relationship:

$$\frac{(\mu_T - \mu_R)^2 + \sigma_D^2}{\sigma_w^2} = \frac{2\delta\sigma_D + (\delta - \sigma_D)^2}{\sigma_w^2},$$

where $\delta = \mu_T - \mu_R$. When δ and σ_D are close, we observe that

$$\frac{\delta^2 + \sigma_D^2}{\sigma_w^2} \approx \frac{2\delta\sigma_D}{\sigma_w^2}.$$

The assumption is reasonable when both δ and σ_D are small.

Thus, the proposed SCDI is

$$-\log(\text{BELS}) \leq \left(\frac{\mu_T - \mu_R}{\sigma_w} \right) \left(\frac{2\sigma_D}{\sigma_w} \right) \leq \log(\text{BELS}).$$

Now, let $f = \sigma_w/(2\sigma_D)$, a correction factor for drug interchangeability. Then, the proposed SCDI is given by

$$-\log(\text{BELS})f\sigma_w \leq \mu_T - \mu_R \leq \log(\text{BELS})f\sigma_w. \quad (5)$$

Note that statistical properties and finite sample performance need further research.

ALTERNATIVE CRITERION BASED ON REVERSE OF TEST AND REFERENCE PRODUCT

As indicated by the FDA, an approved generic (test) drug product can serve as a substitute for the innovative (reference) drug product, provided the generic drug product has been shown to be bioequivalent to the innovative drug product. A test product is said to be bioequivalent to a reference product if the 90% confidence interval for the GMR (i.e., μ_T/μ_R), say (L_1, U_1) , is totally within the bioequivalence limit (0.8, 1.25). Based on the similar idea, a reference product can serve as a substitute for a test product if the reference product is shown to be bioequivalent

to the test product (i.e., the test product is now considered the *reference* product in the *new* bioequivalence assessment). In other words, the 90% confidence interval for the GMR of μ_R/μ_T , say (L_2, U_2) , is totally within the bioequivalence limit (0.8, 1.25). In this case, we conclude that the test (*T*) product and the reference (*R*) product can be used interchangeably.

Let *A* be the event that $(L_1, U_1) \subset (0.8, 1.25)$ and *B* be the event that $(L_2, U_2) \subset (0.8, 1.25)$. Define $p_1 = P(\text{Switch from } T \text{ to } R) = P(A)$ and $p_2 = P(\text{Switch from } R \text{ to } T) = P(B)$. In practice, we would expect that $p_1 > p_2$. p_2 is expected to be low at extreme cases, i.e., $(L_2, U_2) \subset (0.8, 1.25)$ at either lower end or upper end. For interchangeability, we would expect that $p_3 = P(\text{Switch from } T \text{ to } R \text{ and switch from } R \text{ to } T) = P(A \text{ and } B)$ is greater than $\max(p_1, p_2)$. For a given bioequivalence study, point estimates and the corresponding confidence intervals for p_i , $i = 1, 2, 3$ are necessarily obtained for the evaluation of the proposed criterion for drug interchangeability.

DESIGN FOR DRUG INTERCHANGEABILITY

Balaam's Design

Balaam's design is a 4×2 crossover design, denoted by (*TT*, *RR*, *TR*, *RT*). Under a 4×2 Balaam's design, qualified subjects will be randomly assigned to receive one of the four sequences of treatments: *TT*, *RR*, *TR*, and *RT*. For example, subjects in sequence 1 of *TT* will receive the test (biosimilar) product first and then crossed over to receive the reference (innovative biological) product after a sufficient length of washout. In practice, a Balaam's design is considered the combination of a parallel design (the first two sequences) and a crossover design (sequences 3 and 4). The purpose of the part of parallel design is to obtain independent estimates of intra-subject variabilities for the test product and the reference product. In the interest of assigning more subjects to the crossover phase, an unequal treatment assignment is usually employed. For example, we may consider a 1:2 allocation to the parallel phase and the crossover phase. In this case, for a sample size of $N = 24$, 8 subjects will be assigned to the parallel phase and 16 subjects will be assigned to the crossover phase. As a result, four subjects will be assigned to sequences 1 and 2, while eight subjects will be assigned to sequences 3 and 4, assuming that there is a 1:1 ratio treatment allocation within each phase. Under the 4×2 Balaam design, the following comparisons are usually assessed:

1. Comparisons by sequence
2. Comparisons by period
3. *T* vs *R* based on sequences 3 and 4—this is equivalent to a typical 2×2 crossover design
4. *T* vs *R* given *T* based on sequences 1 and 3
5. *R* vs *T* given *R* based on sequences 2 and 4

6. Comparison between (1) and (3) for assessment of the treatment-by-period interaction

It should be noted that the interpretations of the above comparisons are different. More information regarding statistical methods for data analysis of Balaam's design can be found in the work of Chow and Liu.^[7]

Two-Sequence Dual Design

Two-sequence dual design is a 2×3 higher order cross-over design consisting of two dual sequences, namely, *TRT* and *RTR*. Under the two-sequence dual design, qualified subjects will be randomly assigned to receive either the sequence of *TRT* or the sequence of *RTR*. Of course, there is a sufficient length of washout between dosing periods. Under the two-sequence dual design, we will be able to evaluate the relative risk of alternating between the use of the biological product and reference products and the risk of using the reference product without such alternating.

Note that expected values of the sequence-by-period means, analysis of variance table, and statistical methods (e.g., the assessment of average biosimilarity, the inference on carryover effect, and the assessment of intra-subject variabilities) for analysis of data collected from a two-sequence dual design are given in the work of Chow and Liu.^[7] In case there are missing data (i.e., incomplete data), statistical methods proposed by Chow and Shao^[8] are useful.

Modified Balaam's design

As indicated earlier, Balaam's design is useful for addressing switching, whereas two-sequence dual design is appropriate for addressing alternating. In the interest of addressing both switching and alternating in a single trial, we may combine the two study designs as follows: (*TT*, *RR*, *TRT*, *RTR*), which consists of a parallel design (the first two sequences) and a two-sequence dual design (the last two sequences). Data collected from the first two dosing periods (which are identical to the Balaam design) can be used to address switching, whereas data collected from sequences 3 and 4 can be used to assess the relative risks of alternating.

Complete Design

As it can be seen that the modified Balaam design is not a balanced design in terms of the number of dosing periods. In the interest of balance in dosing periods, it is suggested the modified Balaam design be further modified as (*TTT*, *RRR*, *TRT*, *RTR*). We will refer to this design as a complete design. The difference between the complete design and the modified Balaam design is that the treatments are repeated at the third dosing period for sequences 1 and 2. Data collected from sequence 1 will provide a more

accurate and reliable assessment of intra-subject variability, whereas data collected from sequence 2 is useful in establishing baseline for the reference product. Note that statistical methods for analysis of data collected from the complete design are similar to those under the modified Balaam design.

Alternative Designs

For assessment of IBE under a replicated design, Chow et al.^[9] indicated that the optimal design among 2×3 crossover designs is the so-called extra-reference design, which is given by (TRR, RTR). Thus, an alternative design is to combine a parallel design (TTT, RRR) and a 2×3 extra-reference design for addressing both switching and alternating. The resultant study design is then given by (TTT, RRR, RTR, TRR).

Adaptive Designs

In recent years, the use of adaptive design methods in clinical research has become very popular due to its flexibility and efficiency for identifying any (or optimal) clinical benefits of the test treatment under investigation (see, e.g., the work of Chow and Chang^[10]). Similar ideas can be applied for the assessment of biosimilarity and interchangeability of biosimilar products. For example, a two-stage adaptive design that combines two independent studies into a single trial may be useful. Some adaptations (modifications or changes) can be implemented at the end of the first stage after the review of accumulated data collected from the first stage. More information regarding various adaptive trial designs can be found in the work of Chow and Chang.^[10]

POWER ANALYSIS FOR SAMPLE SIZE

Sample size determination for the assessment of drug interchangeability is an important issue in bioequivalence assessment for generic approval regardless of the criteria used as described in Section “Design for Drug Interchangeability.” In what follows, sample size calculation under the criteria described previously are briefly discussed.

Testing for PBE/IBE

For assessment of PBE and IBE, the FDA recommends that a replicated crossover design (e.g., a 2×3 dual crossover design or a 2×4 replicated crossover design), which provides independent estimates of intersubject variability, intra-subject variability, and variability due to subject-by-treatment interaction, be used for achieving a desired power. As an example, for the assessment of PBE under a 2×4 replicated crossover design, when $n_1 = n_2 = n$, an approximate formula for determination of n (assuming that $n_1 = n_2 = n$) is given by

$$n \geq \frac{2\delta^2\sigma_{1,1}^2 + \sigma_{TT}^2 + c^2\sigma_{TR}^4 - 2c\rho^2\sigma_{BT}^2\sigma_{BR}^2}{\lambda^2} (z_{1-\alpha} + z_\beta)^2, \quad (6)$$

where $\delta = \mu_T - \mu_R$, $(\sigma_{WT}^2, \sigma_{WR}^2)$, and $(\sigma_{BT}^2, \sigma_{BR}^2)$ are within-subject variabilities for the test and reference products and between-subject variabilities for the test and reference products, respectively; $\sigma_{1,1}^2 = \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho\sigma_{BT}\sigma_{BR} + \sigma_{WT}^2 + \sigma_{WR}^2$; and

$$c = \begin{cases} 1 + \theta_{PBE} & \text{if } \sigma_{TR}^2 \geq \sigma_0^2 \\ 1 & \text{if } \sigma_{TR}^2 < \sigma_0^2 \end{cases}$$

for a set of given values of δ , $\sigma_{1,1}^2$, σ_{TT}^2 , σ_{TR}^2 , σ_{BT}^2 , σ_{BR}^2 , and ρ , where z_t is the t th quantile of the standard normal distribution, and $1 - \beta$ is the desired power. Similarly, under a replicated crossover design (e.g., a 2×3 dual design or a 2×4 replicated crossover design), sample size for the assessment of IBE can be determined (see, e.g., the work of Chow et al.^[9]).

Sample Size Determination

For average bioequivalence assessment under a standard 2×2 standard crossover design, Chow and Liu^[7] provided a formula for determination of the required sample size for achieving a $1 - \beta$ power at the α nominal level (assuming that $n_1 = n_2 = n$) as follows:

$$n \geq 2 \left[t(\alpha, 2n-2) + t(\beta, 2n-2) \right]^2 \left(\frac{\hat{\sigma}_d}{\Delta - \delta} \right)^2, \quad (7)$$

where $\delta = \mu_T - \mu_R$, Δ is the equivalence limit, and $\hat{\sigma}_d$ is given by

$$\hat{\sigma}_d^2 = \frac{1}{n_1 + n_2 - 2} \sum_{k=1}^2 \sum_{i=1}^{n_k} (d_{ik} - \bar{d}_k)^2,$$

where $d_{ik} = \frac{1}{2}(Y_{i2k} - Y_{i1k})$, $i = 1, \dots, n_k$, $k = 1, 2$, and $\bar{d}_k = \frac{1}{n_k} \sum_{i=1}^{n_k} d_{ik}$, $k = 1, 2$, in which Y_{ijk} is the response of the i th subject

in the k th sequence at the j th period. For the multiplicative model, we consider the (0.8, 1.25) as the bioequivalence limit for $\delta = \mu_T/\mu_R$ and μ_T and μ_R are the median bioavailabilities of the test and reference formulations, respectively. Similarly, the sample size n required to achieve a $1 - \beta$ power at the α nominal level after the logarithmic transformation is determined by the following equations:

$$n \geq 2 \left[t(\alpha, 2n-2) + t(\beta, 2n-2) \right]^2 [CV/\log(1.25)]^2 \quad \text{if } \delta = 1,$$

$$n \geq 2 \left[t(\alpha, 2n-2) + t(\beta, 2n-2) \right]^2 [CV/(\ln(1.25) - \log\delta)]^2 \quad \text{if } 1 < \delta < 1.25,$$

and

$$n \geq 2 \left[t(\alpha, 2n-2) + t(\beta, 2n-2) \right]^2 \left[CV / (\ln(0.8) - \log \delta) \right]^2 \\ \text{if } 0.8 < \delta < 1$$

where $\ln$ denotes the natural logarithm and $CV = \sqrt{\exp(\sigma^2) - 1}$, the coefficient of variation in the multiplicative model, and σ^2 is the residual (within-subject) variance on the log scale. As a result, for sample size determination based on SCDI, the required sample size for achieving a $1 - \beta$ power at the α level of significance can be obtained by simply replacing Δ given in Eq. 7 with $\Delta' = \Delta f \sigma_w$.

SAMPLE SIZE BASED ON REVERSE OF T AND R

As discussed in Section “Sample Size Determination,” under a standard 2×2 crossover design, by formula (7) the sample size required for switching from T to R can be obtained, say n_1 . Using the same formula (7), the sample size required for switching from R to T can be similarly obtained, say n_2 . As a result, under the proposed p_3 criterion for drug interchangeability, the sample size required for achieving a $1 - \beta$ power at the α level of significance is then given by $n = \max(n_1, n_2)$.

CONCLUDING REMARKS

In practice, as indicated by regulatory agencies such as the FDA, approved generic drug products can be used as a substitute for the innovative drug product; it is a concern whether these approved generic drug products can be used interchangeably in terms of their quality, safety, and efficacy compared to the innovative drug product. It also recognized that bioequivalence assessment based on average bioavailability by ignoring the heterogeneity in variabilities between the test and reference products does not guarantee drug interchangeability. Although some criteria for drug interchangeability such as PBE and IBE^[1,2] have been proposed in the last decade, none of these criteria work satisfactorily for addressing drug prescribability and switchability. On the other hand, the SCDI criterion adjusted for the intra-subject variability and the variability due to subject-by-treatment interaction proposed by Chow

et al.^[5] seems reasonable. The newly proposed criterion by reversing the test and reference products may provide a simple answer to a complicated problem.

The proposed criteria for drug interchangeability for generic approval of small-molecule drug products can be directly applied to the assessment of interchangeability for biosimilar products. However, further evaluation of their statistical properties and/or performances are necessarily conducted.

Drug Interchangeability: Meta-Analysis for Safety Monitoring

Wen-Wei Liu and Shein-Chung Chow

Department of Biostatistics and Bioinformatics, Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

When an innovative (brand-name) drug is going off patent protection, pharmaceutical or generic companies may file an abbreviated new drug application for generic approval. As indicated by the U.S. Food and Drug Administration (FDA), an approved generic drug can be used as a substitute for the brand-name drug. FDA, however, does not indicate that approved generic drugs of the same brand-name drug can be used interchangeably. As more generic drugs become available in the marketplace, it is a concern whether the approved generic drugs are safe and can be used interchangeably. In this entry, we propose two safety margins as new bioequivalence limits for monitoring drug interchangeability based on a meta-analysis of data obtained from regulatory submissions which have been approved by FDA. In addition to the monitoring of drug interchangeability of generic drugs, the proposed margins can also be extended to address drug interchangeability of biosimilars.

Keywords: Drug interchangeability; Safety margins for safety monitoring; Switchability; Prescribability.

INTRODUCTION

When an innovative (brand-name) drug is going off patent protection, the innovative drug companies and/or generic drug companies may file an abbreviated new drug application (ANDA) for generic approval through the conduct of a bioequivalence study. Bioequivalence testing for generic approval is based on the Fundamental Bioequivalence Assumption that when two drug products have similar drug absorption profiles (or equivalent in average bioavailability), it is assumed that they will reach similar therapeutic effects or they are therapeutic equivalent. For an approved generic drug product, the United States Food and Drug Administration (FDA) indicates that it can be used as a substitute of the brand-name drug.

As more generic drug products are available in the marketplace, it is a concern whether the approved generic drugs work as well as the brand-name drug in terms of quality and safety. In practice, it is very common that patients may switch from one generic to another depending upon the availability and inexpensiveness of the generic drugs. Thus, it is a concern that such a switch from a generic drug (e.g., approved on the lower end of bioequivalence limit) to another (e.g., approved on the higher end of bioequivalence limit) could cause a drastic change in blood concentration and consequently cause a safety concern. This issue is critical not only for generic drugs of small molecular innovative drugs but also for biosimilars, which are (large molecular) similar biologic drug products.

In this entry, safety monitoring procedures based on meta-analysis of data available in approved regulatory submissions (e.g., ANDA for generic approval) is proposed. The proposed margins can be extended to monitoring the safety of drug interchangeability of biosimilar drug products.^[1] The entry is organized as follows. The section “Bioequivalence and Drug Interchangeability” provides outline of the bioequivalence and the most common decision rule and then describes why interchangeability might be the issue. The section “Meta-Analysis for Safety Monitoring” briefly reviews what general meta-analysis should consider and how to fit it to our simulation study mathematically. The proposed margins and simulated results are given in the section “Safety Margins for Monitoring Drug Interchangeability and Simulation Study.” There are some differences and similarities between generic drug products and biosimilars, and application of the results to biosimilars is discussed in section “Application to Biosimilars” and section “Conclusion” gives the concluding remarks.

BIOEQUIVALENCE AND DRUG INTERCHANGEABILITY

Bioequivalence

When the innovative drugs want to get the approval from FDA, the pharmaceutical companies have to file new drug applications (NDA). However, for the generic drugs which

are identical to the innovative (brand-name) drugs, they only need to file ANDA which lack the process of animal studies as well as clinical safety and efficacy trials compared to NDA.^[2] The U.S. Federal Food, Drug, and Cosmetic Act (FDCA), enacted by Congress in 1938, gives authority to FDA, and provisions for generic drugs were added in 1984 as *Drug Price Competition and Patent Term Restoration Act*. It states that rate and extent of drug absorption must be compared to establish bioequivalence between two products. Bioavailability of a drug can be described as the extent and rate of the absorption of active drug ingredient from the drug product to the site intended to treat, and it is usually measured by the area under the blood or plasma concentration-time curve (AUC) and the maximum concentration ($C_{\max}$), respectively. The FDA's regulations are codified in Title 21 of the Code of Federal Regulations (21 CFR) which clearly defines $C_{\max}$ as index of rate of absorption and AUC as index of extent of absorption. If the drug is not absorbed from bloodstream, bioavailability can also be assessed by measurements intended to reflect the extent and rate. A comparative bioavailability study indicates the comparison of bioavailabilities of different formulations of the same drug or different drug products, and they are claimed bioequivalent when assuming that they will provide the same therapeutic effect or that they are therapeutically equivalent.

"If two drug products are shown to be bioequivalent, it is assumed that they will generally reach the same therapeutic effect or they are therapeutically equivalent" stated by Chow and Liu^[3] is known as the Fundamental Bioequivalence Assumption, and bioequivalence assessment for generic drug approval should be conducted under this assumption. However, there are four possible scenarios in practice and only one indicates this assumption. The second scenario indicates that the two drug absorption profiles are not similar but they are therapeutically equivalent, and this is the case that generic drug companies might argue when their generic products fail to meet regulatory requirements. The third scenario indicates that the two drug absorption profiles are similar but they are actually not therapeutically equivalent, and innovative drug companies usually argue the inefficacy of the generic copies under this scenario. The fourth scenario is the worst one which indicates that the two drug absorption profiles are not similar and they are not therapeutically equivalent. Therefore, Fundamental Bioequivalence Assumption has been criticized that it is not based on scientific considerations.

80/125 Decision Rule

There are many decision rules for the evaluation of average bioequivalence. The ± 20 rule was applied to assess average bioequivalence in the early 1980s. During the same time, it was suggested that the 80/20 rule be used as the secondary analysis to support the ± 20 rule. However, since the two rules may result in different conclusions with some

possible practical issues, FDA recommended the 80/125 rule be used based on the log-transformed data.^[3]

FDA guidance^[4] suggested that the log-transformation on AUC and $C_{\max}$ be considered. Thus, if the 90% confidence interval (CI) for the geometric mean ratio (GMR) for average bioequivalence of the test formulation over the reference formulation is within (80.00%, 125.00%), then the bioequivalence can be concluded. The range for the criterion is $\ln(0.80) = -0.2231$ to $\ln(1.25) = 0.2231$, and it is symmetric about $\ln(1.00) = 0$, where the test formulation is totally equivalent to the reference formulation.^[3]

Drug Interchangeability

When the generic drugs get the approvals from FDA, it does not indicate that approved generic drugs and the innovative drugs can be used interchangeably. The FDA only indicates that approved generic drugs can be used as a substitute to the innovative drugs. Drug interchangeability for generic drugs can be classified as prescribability or switchability.^[5,6] However, we used average bioequivalence in this entry to simplify this problem since it is the usual method to assess the bioequivalence.

Drug prescribability is described as the physician's decision to prescribe the brand-name drug or its generic copies under the condition that they can be used interchangeably in terms of efficacy and safety. If brand-name drug and its generic copies are bioequivalent in both average and variability, it can be claimed as *population bioequivalence* (PBE) which is usually used to clarify drug prescribability.^[6] PBE is usually applied to new formulations, additional strengths, or new dosage forms in NDAs. Drug switchability is indicated as the exchangeability within the same subject. It can be referred as from brand-name drug to generic copy or from a generic drug to the other generic copies. Drug switchability is ensured by *individual bioequivalence* (IBE) which describes that the majority of subjects satisfy the criteria.^[5] IBE should be considered for ANDA or abbreviated antibiotic drug application for generic drugs. However, there has been a debate on the criteria recommended by FDA; so FDA suggests the method of small-sample CI approach proposed by Hyslop, Hsuan, and Holder be considered for the assessment of PBE/IBE for statistical analysis.^[7]

META-ANALYSIS FOR SAFETY MONITORING

In general, meta-analysis combines small studies for a systematic review. In practice, the sample sizes of some studies might be relatively small. In addition, some trials may fail to show statistically significant treatment effects. Thus, by combining these studies, meta-analysis can provide a more accurate and reliable assessment of the treatment effect under investigation.

In order to achieve the ultimate goals of better accuracy and reliability of the treatment effect, the following

general principles need to be taken into consideration when performing a meta-analysis.

1. It is often a concern that only positive clinical studies are included in the meta-analysis, which may have introduced selection bias. To avoid this, criteria for selection of studies and the time period to be included in the meta-analysis need to be clearly stated in the study protocol. If there is a potential trend over time, a statement need to be provided for scientific justification for inclusion of the studies selected.
2. It is critical to assess similarity and dissimilarity among studies to reduce variability for a more accurate and reliable assessment of the test treatment under investigation, because different studies may be conducted with similar but different study protocols, drug products and doses, patient populations, sample sizes, evaluability criteria, and so on.
3. Before the data sets obtained from different studies can be combined for a meta-analysis, it is suggested that a statistical test for probability be performed to determine whether there is significant treatment-by-study interaction.

Meta-Analysis

For each study trial, 90% CI for log-transformed data can be constructed. If it is within the range of 80% to 125%, then bioequivalence is claimed. However, generic approval criteria based on the average bioequivalence has the limitation that cannot guarantee the drug interchangeability. If any trial has lower bound L^* which is lower than L (lower margin) but higher than 80% or the upper bound U^* is higher than U (upper margin) but lower than 125%, then it might have the safety concern since the relative change of concentration of the drug in blood is dramatic. Assume the bioequivalence of the generic drug, a patient used for a long period was close to 125%, and a physician switches to another generic drug which with bioequivalence close to 80%. We may wonder if the new generic drug can still be used to heal the patient as efficient as the old one because the concentration of the drug in blood decreases $\frac{(125-80)}{125} = 36\%$ to the original. Correspondingly, the concentration of the drug in blood may also increase $\frac{(80-125)}{80} = 56\%$ to the original. By doing the meta-analysis in different clinical trials for the same brand-name drug, we will have several margins as the monitoring tool to evaluate all generic drugs and to calculate $P(L^* < L)$ and $P(U^* > U)$ as the probability of the improper rate.

From the previous study by Chow and Liu,^[8] a meta-analysis for a systemic overview of bioequivalence was proposed. Suppose there are K different trials for the same brand-name drug. Follow the assumptions below:

1. The same standard two-sequence, two-period crossover design was constructed with n_{k1} and n_{k2} at sequence 1 and 2, where $k = 1, \dots, K$.

2. The same statistical model for 2×2 crossover design was used for log-transformed data to assess bioequivalence.
3. Intersubject variabilities are the same for all subjects. ($\sigma_{sk}^2 = \sigma_s^2$ for all k .)
4. Intrasubject variabilities are the same for all subjects. ($\sigma_{ek}^2 = \sigma_e^2$ for all k .)

To combine the data from the K studies, we first test for the homogeneity of the reference products among the K studies. We can derive the following χ^2 distribution with $K - 1$ degrees of freedom to test homogeneity:

$$\chi_R^2 = \sum_{k=1}^K \frac{1}{C_k} (\bar{Y}_{Rk} - \hat{\mu}_R)^2 \quad (1)$$

where adjusted parameter,

$$C_k = \frac{1}{4} \left(\frac{1}{n_{k1}} + \frac{1}{n_{k2}} \right) \quad (2)$$

and unbiased estimator,

$$\hat{\mu}_R = \sum_{K=1}^K \left(\frac{\frac{1}{C_k(\sigma_e^2 + \sigma_s^2)} \bar{Y}_{Rk}}{\sum_{k=1}^K \frac{1}{C_k(\sigma_e^2 + \sigma_s^2)}} \right) = \sum_{K=1}^K \left(\frac{\frac{1}{C_k} \bar{Y}_{Rk}}{\sum_{k=1}^K \frac{1}{C_k}} \right) \quad (3)$$

and $\bar{Y}_{Rk}$ is the least squares mean of the reference product of the k^{th} study.

Reject the null hypothesis of homogeneity at the α level of significance if:

$$\chi_R^2 > \chi^2(\alpha, K - 1) \quad (4)$$

If we fail to reject the null hypothesis of homogeneity, we can combine drug effect and get the corresponding CIs. Let,

$$\hat{d}_k = \bar{Y}_{Tk} - \bar{Y}_{Rk}, k = 1, \dots, K \quad (5)$$

be the difference of the least squares means between the test product and the reference product of the k^{th} study. If we assume that μ_{Tk} , $k = 1, \dots, K$, are the same for all studies ($\mu_{Tk} = \mu_T$ for all k), a combined estimate for $\mu_T - \mu_R$ is the weighted means of $\hat{d}_k$, i.e.,

$$\bar{d} = \sum_{k=1}^K \left(\frac{\frac{1}{C_k} \bar{d}_k}{\sum_{k=1}^K \frac{1}{C_k}} \right) \quad (6)$$

where,

$$\text{Var}(\bar{d}) = \frac{\sigma_e^2}{\sum_{k=1}^K \frac{1}{C_k}} \quad (7)$$

Then a $(1 - 2\alpha) \times 100\%$ CI, denoted by (L_m, U_m) , can be obtained as follows:

$$(L_m, U_m) = \bar{d} \pm t\left(\alpha, \sum_{k=1}^K (n_{k1} - n_{k2} - 2)\right) \sqrt{\hat{V}(\bar{d})} \quad (8)$$

SAFETY MARGINS FOR MONITORING DRUG INTERCHANGEABILITY AND SIMULATION STUDY

The studies in meta-analysis are all approved generic drugs, so the 90% confidence intervals are all located within (80%, 125%). However, as described in section “Meta-analysis,” it might have some concerns while switching from one generic drug to another. Therefore, safety margin for interchangeability cannot use (80%, 125%), and if applying (L_m, U_m) , drug concentration in blood will not change so much, so it could be selected as a margin. However, it is too narrow and strict, for example, $(L_m, U_m) = (95\%, 105\%)$, so several margins to monitor the drug interchangeability are proposed. The hypothesis can be expressed as follows:

$$\begin{aligned} H_0: \frac{(|L - U|)}{L} \leq \tau \text{ and } \frac{(U - L)}{L} \leq \tau \text{ versus} \\ H_1: \frac{(|L - U|)}{L} > \tau \text{ or } \frac{(U - L)}{L} > \tau \end{aligned} \quad (9)$$

Safety Margins for Monitoring Drug Interchangeability

Margin1 (M1). Let (L_m, U_m) be the 90% CI obtained from a meta-analysis. Set $L_1 = L_m - \delta_L$ and $U_1 = U_m - \delta_M$, where $\delta_L = (L_m - 0.8)/2$ and $\delta_M = (1.25 - U_m)/2$. Actually, L_1 is in the middle of 0.8 and L_m , and U_1 is in the middle of 1.25 and U_m . (L_1, U_1) is our first set of margins.

Margin2 (M2). For each meta-analysis, we can get the lower margin (L) which is smaller than 95% of the lower bounds (L^*) from the 90% CI of different studies, and it can be expressed as $P(L^* \geq L_2) = 95\%$. Correspondingly, the upper margin (U) is larger than 95% of the upper bound (U^*) from the 90% CI of different studies, and it can be expressed as $P(U^* \leq U_2) = 95\%$. Therefore, L_2 will be like the 5th percentile of the boundaries, and U_2 will be the 95th percentile of the boundaries. Since we will simulate 20 data sets for a meta-analysis, L_2 is the second smallest lower bound and U_2 is the second largest upper bound.

Margin3 (M3) and **Margin4 (M4)** are similar to M2 but with different probability. For **Margin3**, it is $P(L^* \geq L_3) = 90\%$, $P(U^* \leq U_3) = 90\%$. For **M4**, it is $P(L^* \geq L_4) = 85\%$, $P(U^* \leq U_4) = 85\%$ (Fig. 1).

Fig. 1 Relationships among BE limits, meta-analysis confidence limits, M1, M2, M3, and M4

Simulation Study

All the studies in meta-analysis are approved generic drugs, so the data are regulated by FDA and we cannot get these real data. Therefore, the simulation study is conducted. In this study, we simulate 24 subjects in a data set and 20 data sets as one meta-analysis study, and we simulate 1000 meta-analysis studies from one scenario. There are six scenarios in this study (Table 1). For each scenario, there is the average meta-analysis 90% CI derived by the formula in section “Meta-Analysis” (Table 2). The margins (M1–M4) for each scenario (S1–S6) can also be obtained by the definition in section “Safety Margins for Monitoring Drug Interchangeability.” The probability of the 90% CI for a study below the lower margin (below L) or above the upper margin (above U) can be calculated. Safety impact is when the efficacy of original drug is close to the lower margin and suddenly change to the drug with efficacy close to the upper margin, which is calculated as $\frac{(|L - U|)}{L}$ (low to high), correspondingly, efficacy impact is calculated as $\frac{(U - L)}{U}$ (high to low).

The 90% CI obtained from meta-analysis is usually narrower than the CI from one study, so we adjust it by δ . From Table 2, we can see that the CIs are similar when the true variances (σ_s^2, σ_e^2) are the same, and they get larger when the true variances become larger. In addition, the probability of the CI for a study lower than the lower margin (below L) or higher than the upper margin (above U) are all 0.050 for M2, 0.100 for M3, and 0.150 for M4 since it is the definition for these margins. However, the safety/efficacy impact seems to be smaller when the true mean (μ) is larger. It is not surprising that when the true variance gets larger, the safety/efficacy impact also gets larger. In addition, the below L and above U have the same situation as the safety/efficacy impact, and they dramatically increase for M1 when variance gets larger. M1, M2, M3, and M4 are similar when variances are small. However, when variances get larger, they perform differently and

	M4		(0.831, 1.202)	0.150	0.150	0.446	0.308
S6	M1	(0.972, 1.025)	(0.886, 1.138)	0.889	0.860	0.284	0.221
	M2		(0.806, 1.241)	0.050	0.050	0.541	0.351
	M3		(0.809, 1.236)	0.100	0.100	0.529	0.346
	M4		(0.812, 1.232)	0.150	0.150	0.518	0.341

M1 is usually the narrowest one. From regulatory point of view, if we choose the criterion for safety/efficacy impact is 30%, that is, $\tau = 0.3$ in the hypothesis, then we can see when the variance is small, all margins can meet this criterion. However, the variance in real data is usually located between 20 and 30, and we can see that only M1 meets this criterion. Therefore, the proposed M1 is a useful tool for safety monitoring for interchangeability.

APPLICATION TO BIOSIMILARS

Biosimilars are the biological drug products that are made from living organisms by means of recombinant DNA or controlled gene-expression methods, which is also known as follow-on biologics; as indicated by Chow,^[9] there are fundamental differences between generic drugs and biosimilars (Table 3). As can be seen in Table 3, generic drug products have a well-defined structure and can be characterized, while biosimilars are difficult to characterize due to their heterogeneous and complicated structures with mixtures of various molecules. Thus, generic drug products are usually relatively stable. However, since

Table 3 Fundamental differences between generic drug products and biosimilars

Generic drug products	Biosimilars
Made by chemical synthesis	Made by living cells or organisms
Defined structure	Heterogeneous structure mixtures of related molecules
Easy to characterize	Difficult to characterize
Relatively stable	Variable and sensitive to environmental conditions, such as light and temperature
No issue of immunogenicity	Issue of immunogenicity
Usually taken orally	Usually injected
Often prescribed by a general practitioner	Usually prescribed by specialists

biosimilars are derived from living cells or organisms, they have the biological property which is variable and sensitive to environmental conditions such as light and temperature. A slight change or variation during the manufacturing process may result in different function, efficacy, and safety.

In addition, unwanted immune response is the worst result of biosimilars which may cause a loss of efficacy or cause some safety issues.

However, the basic concept of statistical method used to assess bioequivalence for generic drugs and biosimilarity for biosimilars are consistent (ex. the 80/125 decision rule), so we could apply the results in this entry to biosimilars. In Europe, generic versions of biological drug products are administrated by European Medicines Agency (EMA), and are defined as a “version of an already authorized biological medicinal product with demonstrated similarity in quality characteristics, biological activity, efficacy and safety, based on a comprehensive comparability exercise.”^[10] They have issued several guidelines describing overarching and specific biosimilar. In the United States, the approval for generic versions of biological drug products is based on *Biologics Price Competition and Innovation (BPCI) Act*, which was originally sponsored and introduced in June 26, 2007 by Senator Edward Kennedy (D-MA) and written into law on March 23, 2010. As indicated in the *BPCI Act*, a biosimilar product is defined as a product that is “highly similar” to an already-approved biological product clinically in terms of safety, purity, and potency, notwithstanding minor differences in clinically inactive components. Here, purity may be related to some important quality attributes at critical stages of the manufacturing process, and potency has something to do with the stability and efficacy of the biosimilar product.

The *BPCI Act* seems to suggest that a biosimilar product should be highly similar (sufficiently close) to the reference drug product in all spectrums of good drug characteristics such as identity, strength (potency), quality, purity, safety, and stability as described in the United States Pharmacopeia and National Formulary (USP/NF). In addition, FDA draft guidance^[11] suggests “stepwise approach” and the concept of “totality-of-the-evidence.” This indicates that the FDA is interested in demonstrating global similarity in all aspects related to safety, purity, and potency of the biosimilar products, but it is almost impossible to demonstrate that a biosimilar product is highly similar to the reference product in all aspects of good drug characteristics in a single study. Thus, to ensure that a biosimilar product is highly similar to the reference product in terms of these good drug characteristics, biosimilar studies for different aims may be required. For example, if safety and efficacy are the concern, then a clinical trial must be conducted to demonstrate that there are no clinically meaningful differences in terms of safety and efficacy between a biosimilar product and the innovator biological product. On the other hand, to ensure that important quality attributes are highly similar, critical stages of the manufacturing process, assay development/validation, process control/validation, and product specification of the reference product should be necessarily established through the conduct of relevant studies.

Similar to the Fundamental Bioequivalence Assumption, Chow et al.^[12] proposed the following Fundamental Biosimilarity Assumption for follow-on biologics—When a biosimilar product is claimed to be biosimilar to an innovator’s product based on some well-defined product characteristics, it is therapeutically equivalent, provided that the well-defined product characteristics are validated and are reliable predictors of safety and efficacy of the products. Unlike the Fundamental Bioequivalence Assumption that assumes that equivalence in the exposure measures implies therapeutical equivalence, Fundamental Biosimilarity Assumption has to verify that some validated product characteristics are indeed reliable predictors of safety and efficacy.

However, generic drugs and biosimilars are slightly different in drug interchangeability. As indicated in the subsection (k)(4) of the *Public Health Act subsection 351(k)(4)*, of the *BPCI Act*, the term interchangeable or interchangeability in reference to a biological product, means that the biological product may be biosimilar to the reference product and expected to produce the same clinical result in any given patient. In addition, the biological product may also be substituted for the reference product without the intervention of the health care provider who prescribed the reference product. However, unlike the interchangeability of small-molecule drug products, which could be described as prescribability and switchability, the FDA considers interchangeability includes the concepts of switching and alternating between an innovative biologic product (R) and its biosimilars (T). The concept of switching involves the switch from not only “R to T” or “T to R” but also “T to T” and “R to R.” As a result, in order to assess switching, biosimilarity for “R to T,” “T to R,” “T to T,” and “R to R” needs to be assessed based on some biosimilarity criteria under a valid study design.

On the other hand, the concept of alternating is referred to as either the switch from T to R and then switch back to T (i.e., “T to R to T”) or the switch from R to T and then switch back to R (i.e., “R to T to R”). Thus, the difference between “the switch from T to R” or “the switch from R to T” and “the switch from R to T” or “the switch from T to R” needs to be assessed for addressing the concept of alternating.

CONCLUSION

The concept of drug interchangeability for generic (small molecule) drug products and biosimilars (generic versions of large molecule biological drug products) is similar but different, and so the interpretation should be carefully handled. Based on the 80/125 rule, it is not usual but it is possible to cause a dramatic change in the concentration of a drug in blood when changing from one drug to another. This change may cause uncertainty in

the safety or efficacy. Based on the margins proposed in this entry, M1 has better ability to control safety and efficacy impact, and so it can be considered as a useful tool for safety monitoring for interchangeability. However, it has a higher probability of the CI for a study below the lower margin (below L), or above the upper margin (above U) indicating that if we set this margin as the new criteria rule rather than 80% to 125%, there will be so many bioequivalence/biosimilar studies that do not meet this criterion. Therefore, drug interchangeability for bioequivalence/biosimilar is a big challenge and we can do a future work to interpret this by using mathematical formula.

Abstract

When the bioequivalence (BE) of a generic product to a reference drug is stated, their interchangeability is generally assumed. This implies that the drug products can be readily switched and substituted. However, it is important to distinguish between the conditions of prescribability and switchability when, respectively, a drug is provided to a patient either for the first time in any of its forms or administered by replacing another formulation of the same drug product. These two conditions are statistically characterized by the regulatory models of population and individual BE. These models embrace important principles.

Keywords: Bioequivalence; Interchangeability; Prescribability, Switchability; Population bioequivalence; Individual bioequivalence.

INTRODUCTION

When the patent of an originally developed drug expires, marketing authorization is often sought for alternative generic drug products. Drugs having small molecules can usually be synthesized chemically. In order to market the alternative, generic drugs and their bioequivalence (BE) with the brand name, the drug must be demonstrated and approved. The generics are then viewed to be as safe and effective as the original drugs. Consequently, they are assumed to be mutually interchangeable. This is expressed in the preface of the *Orange Book* of the Food and Drug Administration (FDA)^[1] as well as in a guideline of the European Medicines Agency (EMA).^[2] The view is confirmed in assurances by FDA commissioners.^[3,4] However, the implementation and application of interchangeability are subject to rules and regulations of the states in the United States (US) and of member nations in the European Union (EU).

Thus, there is a widely applied assumption that the BE of two drug products enables their interchangeability. While the assumption is very often reasonable, it has limitations. Therefore, it is important to keep in mind the distinction between the *prescribability* and *switchability* of drug products.^[5] Two corresponding scenarios can be envisaged.

Under the first scenario, a patient had no prior exposure to a drug in any of its forms, i.e., she/he has been naive to the drug. In such situations, any of the approved products are *prescribable* provided that their safety and efficacy are satisfactory and, therefore, they have been approved by regulators. However, after the patient has started to receive one of the products, it may not be substituted by another formulation.

Under the second scenario, the patient is already taking the drug but opts for a cheaper alternative for economic reasons. In this case, the alternative products must be therapeutically equivalent, so that the products will be *switchable* within individuals. The switch usually occurs from the reference product to the test product (denoted by $R \rightarrow T$).

Switching between marketed drug products can become more general, and they can be entirely *interchangeable*. Directions of switches are possible like the $T \rightarrow R$ and $T \rightarrow T'$ switch; here, T' is a second generic, test product. The products R , T , and T' must be interchangeable in any possible sense to achieve the same therapeutic effect after a switch.

Depending on the condition, two test models were proposed. To describe prescribability quantitatively the so-called *population BE* (PBE) model was developed. This required the comparison of the population distributions for the relevant pharmacokinetic parameters. A simple parallel group design study is considered adequate to establish PBE.

In contrast, interchangeability could be demonstrated by satisfying the requirements of a model for *individual BE* (IBE). The implementation of IBE calls for a more complex study design: IBE requires investigations with a replicated crossover design in which both drug products are measured (at least) twice within individuals.^[6]

The development of population and IBE reflects the approach of the US FDA. These two regulatory models will be described after an introduction to the procedure of average BE. A few remarks will conclude this entry.

AVERAGE BE

BE studies are required for granting marketing authorization for generic medicinal products. The exact requirements slightly differ between main jurisdictions such as the US, the EU, and Japan, but the general approach is similar.

The approval is based on the results of a BE study. The plasma concentrations of the generic (called Test product, T) and the originator (Reference, R) formulations are compared in a limited number (somewhere between 18 and 60 depending upon the associated variability) healthy volunteers in a crossover fashion. Half of the volunteers are randomly assigned to get the Test drug and, after it is eliminated from the body, they receive the Reference product. For the other half of the group the order is reversed, receiving first the Reference and then the Test product. After drug ingestion, several blood samples are obtained and the concentrations of the active substance are determined.

To demonstrate BE, it should be shown that derived parameters from the concentrations, such as the areas under the curve and the maximum concentration of the Test and Reference products, are not really different, but they are similar to each other.

BE is usually evaluated by the two one-sided tests (TOST) procedure. The logarithmic means of the two formulations (μ_T and μ_R , respectively) are compared. The two null hypotheses assume that the deviation between the logarithmic means is either too low:

$$H_{01} : \mu_T - \mu_R \leq -\theta \quad (1)$$

or too high:

$$H_{02} : \mu_T - \mu_R \geq \theta \quad (2)$$

θ is a BE limit which is usually thought to be symmetrical in the two directions. BE is demonstrated if the alternative hypotheses are satisfied:

$$H_{a1} : \mu_T - \mu_R > -\theta \quad (3)$$

and

$$H_{a2} : \mu_T - \mu_R < \theta \quad (4)$$

Another, operationally equivalent procedure to the TOST approach expects that the confidence interval around the difference between the logarithmic means should be between the upper and lower confidence limits:^[7,8]

$$\theta \leq \mu_T - \mu_R \leq \theta \quad (5)$$

The 90% confidence limits are usually between $-\ln(1.25)$ and $+\ln(1.25)$. Consequently, the type I error for both null hypotheses is not higher than 5%.

PBE FOR PRESCRIBABILITY

Schall and Luus^[9] introduced a statistical model for PBE. It was implemented in a statistical guidance of FDA.^[6] It suggests that the criterion for PBE includes not only the (squared) difference between the two means, $\delta^2 = (\mu_T - \mu_R)^2$, but also the difference between the corresponding total variances ($\sigma_{TT}^2 - \sigma_{TR}^2$); the total variances are the sums of the between- and within-subject variances:

$$\theta_p = (\delta^2 + \sigma_{TT}^2 - \sigma_{TR}^2) / \max\{\sigma_{T0}^2, \sigma_{TR}^2\} \quad (6)$$

Here, σ_{T0}^2 is a constant, the magnitude of which is established by regulators. PBE can be claimed if the one-sided 95% upper confidence bound for θ_p is less than a prespecified BE limit.

The model emphasizes that not only the difference between the two means is important but also the difference between the total variances. According to the denominator, θ_p remains at a constant level as long as σ_{TR}^2 does not exceed σ_{T0}^2 . However, θ_p increases at high total variation of the reference formulation.

In view of the above PBE criterion, PBE can be claimed if the null hypothesis in:

$$H_0 : \lambda \geq 0 \text{ vs. } H_a : \lambda < 0 \quad (7)$$

is rejected at the 5% level of significance and the observed geometric means ratio (GMR) is within the limits of 80% and 125%, where:

$$\lambda = \delta^2 + \sigma_{TT}^2 - \sigma_{TR}^2 - \theta_{PBE} \max(\sigma_{TR}^2, \sigma_0^2) \quad (8)$$

and θ_{PBE} is a constant specified in the 2001 FDA draft guidance.

Under a 2×2 crossover design, the one-sided 95% upper confidence bound for θ_p can be obtained under the following model:

$$y_{ijk} = \mu + F_i + P_j + Q_k + S_{ikl} + \epsilon_{ijk} \quad (9)$$

where μ is the overall mean, P_j is the fixed effect of the j^{th} period, Q_k is the fixed effect of the k^{th} sequence, F_i is the fixed effect of the i^{th} drug product, S_{ikl} is the random

effect of the i^{th} subject in the k^{th} sequence under the l^{th} drug product, and ϵ_{ijk} s are independent random errors distributed as $N(0, \sigma_{w1}^2)$. It is assumed that S_{ikl} s and ϵ_{ijk} s are mutually independent. It can be verified that (S_{ikT}, S_{ikR}) , $i = 1, 2, \dots, n_k$; $k = 1, 2$ are independent and identically distributed bivariate normal random vectors with mean 0 and an unknown covariance matrix:

$$\begin{pmatrix} \sigma_{BT}^2 & \rho\sigma_{BT}\sigma_{BR} \\ \rho\sigma_{BT}\sigma_{BR} & \sigma_{BR}^2 \end{pmatrix} \quad (10)$$

where σ_{Bl}^2 denotes the between-subject variability for the l^{th} drug product. Thus, we have:

$$\sigma_{TT}^2 = \sigma_{BT}^2 + \sigma_{WT}^2 \text{ and } \sigma_{TR}^2 = \sigma_{BR}^2 + \sigma_{WR}^2 \quad (11)$$

The means and total variations of the two drug products can be estimated from BE studies with two (or more) parallel groups.

IBE FOR SWITCHABILITY

Schall and Luus^[9] and Sheiner^[10] presented similar statistical models for the determination of IBE. The model was implemented in the statistical guidance of FDA.^[6] The model for IBE contrasts not only the squared deviation between the two means, $\delta^2 = (\mu_T - \mu_R)^2$, but also the difference between the corresponding within-subject variances ($\sigma_{WT}^2 - \sigma_{WR}^2$). It contains also an additional term for the variance component of the subject-by-formulation interaction, σ_D^2 :

$$\theta_1 = (\delta^2 + \sigma_{WT}^2 - \sigma_{WR}^2 + \sigma_D^2) / \max\{\sigma_{w0}^2, \sigma_{WR}^2\} \quad (12)$$

Here, σ_{w0}^2 is a constant, the magnitude of which is set by regulators. IBE can be claimed if the one-sided 95% upper confidence bound for θ_1 is less than a prespecified BE limit.

The IBE model compares the differences between both means and within-subject variances of the two drug products. Furthermore, the interaction between subjects and formulations is considered to be important. However, the procedure proposed for its estimation was questioned.^[11]

The denominator of the IBE model indicates that the magnitude of the criterion θ_1 is constant when σ_{WR}^2 does not exceed σ_{w0}^2 . However, θ_1 increases at high within-subject variations of the reference product.

FDA suggested at the time a value of $\sigma_{w0} = 0.20$.^[6] It recommended in a simplified model of IBE, the so-called reference scaled average BE, $\sigma_{w0} = 0.25$.^[12] EMA suggested $\sigma_{w0} = 0.294$ for a closely related model.^[2]

In view of the above IBE criterion, IBE can be claimed if the null hypothesis in

$$H_0 : \gamma \geq 0 \text{ vs. } H_a : \gamma < 0 \quad (13)$$

is rejected at the 5% level of significance and the observed GMR is within the limits of 80% and 125%, where

$$\gamma = \delta^2 + \sigma_D^2 + \sigma_{WT}^2 - \sigma_{WR}^2 - \theta_{IBE} \max(\sigma_{WR}^2, \sigma_{w0}^2) \quad (14)$$

and θ_{IBE} is a constant specified in the 2001 FDA draft guidance.

For the assessment of IBE, FDA recommends that a replicated 2×2 crossover design, i.e., (TRTR, RTTR) or (RTRT, TRTR) be used. Under the 2×2 replicated crossover design, the one-sided 95% upper confidence bound for θ_1 can be obtained under the following statistical model:

$$y_{ijk} = \mu + F_l + W_{ljk} + S_{ikl} + \epsilon_{ijk} \quad (15)$$

where μ is the overall mean, F_l is the fixed effect of the l^{th} drug product, W_{ljk} s are fixed period, sequence, and interaction effects, S_{ikl} is the random effect of the i^{th} subject in the k^{th} sequence under the l^{th} drug product, and ϵ_{ijk} s are independent random errors distributed as $N(0, \sigma_{w1}^2)$. It is assumed that S_{ikl} s and ϵ_{ijk} s are mutually independent. Under model (9), σ_D^2 is given by:

$$\sigma_D^2 = \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho\sigma_{BT}\sigma_{BR} \quad (16)$$

which is the variance of $S_{ikT} - S_{ikR}$. Note that σ_D^2 is usually referred to as the variance component due to the subject-by-formulation interaction. It can be verified that when $\sigma_{WR}^2 \geq \sigma_{w0}^2$, the linearized criterion γ can be decomposed as follows:

$$\gamma = \delta^2 + \sigma_{0.5,0.5}^2 + 0.5\sigma_{WT}^2 - (1.5 + \theta_{IBE})\sigma_{WR}^2 \quad (17)$$

Individual BE and interchangeability for small-molecule drug products were widely discussed for about a decade starting in the 1990s and eloquent recommendations were made.^[13,14] However, the need for more complicated studies, three- or even more than three-period crossover studies, was questioned.^[15,16]

CONCLUSION

The important concepts of prescribability and switchability should be kept in mind when pharmacokinetic features of two drug products are compared. Regulatory approval means directly an agreement only that they are prescribable, i.e., that the drug products may be provided to a naive patient who has not taken the drug until this point in any form.

For small-molecule generics, it is generally assumed that regulatory approval of BE with a reference drug indicates (or, better, implies) that the two drug products are therapeutically equivalent. Consequently, their free interchangeability is generally also assumed. This also enables

ready substitution of the various products in pharmacies. Since small-molecule drugs are generally safe and effective, these assumptions and practices usually work. However, there are important exceptions.

First, if several generics are bioequivalent to the same drug, then it is not obvious that they are bioequivalent also with each other. Anderson and Hauck^[17] demonstrated that with two or three generics, the probability of such lack of BE is fairly low. However, with five, six, or more products in the market, the concern becomes substantial. Also, strong clinical concerns were repeatedly raised about the safe generic-to-generic substitution of, e.g., antiepileptics^[18,19] and immunosuppressant products.^[20]

Granting the status of “interchangeability” between two drugs will lead to the practice of switching and substitution. Before substitutions of small-molecule products can be considered, regulators must declare that sufficient similarity of the safety and efficacy of the drug products has been demonstrated. With small-molecule, chemical drugs, *sufficient similarity* is usually based on a clearly defined, rigorous statement of the BE between the pharmacokinetic profiles of the contrasted drug products. The comparison typically involves the generic and the reference formulation. Thus, clear, simple regulatory requirements and criteria have been declared for establishing the BE between a small-molecule, generic formulation and a reference product as set out in regulatory guidances.^[2,6,21,22]

The 2001 draft guideline released by the FDA^[6] met serious criticism and was later superseded by another guideline^[23] in which the FDA reverted back to average BE. However, components of the IBE model, including the comparison of within-subject variances and the estimation of the subject-by-formulation variance component, have emerged in some of the FDA guidances.^[24,25] The concept of IBE was acknowledged but was never accepted by the Committee for Medicinal Products for Human Use (CHMP), the European regulatory body.

Ecologic Inference

Sander Greenland

Department of Epidemiology and Department of Statistics, University of California,
Los Angeles, California, U.S.A.

Abstract

This entry emphasizes the nonseparability of contextual (group-level) effects from individual-level effects that arises from the multi-level causal structure of ecological (aggregate) data.

Keywords: Aggregate studies; Contextual effects; Cross-level bias; Ecological bias; Ecological fallacy; Ecological studies.

INTRODUCTION

Ecological data (e.g., health-surveillance data such as vital statistics and registry data) are often collected at great expense and therefore should be exploited fully. They are useful for detecting trends in behaviors, health, and disease; for initial detection and screening of associations; and for describing outcomes across a broader spectrum of exposures than is found in typical cohort or case-control studies. This breadth suggests that the power to detect effects in ecological data would be greater than in cohort or case-control studies, if biases could be controlled. However, ecological data on risk factors and outcomes are usually unlinked on the individual level and thus allow only group-level (ecological or aggregate) associations to be examined.

The limitations of inferences from such data are illustrated in the often-cited characteristic of Florida's population, where people are "born Hispanic and die Jewish." These average characteristics of the state's population tell little about the reality of individuals living in Florida because the birth and death rates are group averages and are not even from the same individuals. Linked birth and death data would show little if any change in ethnic identity over a lifetime. Unlinked data only allow ecological associations to be examined; attempts to draw individual-level inferences or causal inferences (whether individual or group level) may suffer from problems subsumed under the topics of *ecological bias* and *ecological fallacies*. Here I review the theory needed to understand these problems. I emphasize the nonseparability of contextual (group-level) effects from individual-level effects that arises from the multi-level causal structure of ecological (aggregate) data. Contrary to common misperceptions, this problem afflicts ecological studies in which the sole objective is to estimate contextual effects, as well as studies in which the objective is to estimate individual effects. Multi-level

effects also severely complicate causal interpretations of model coefficients.

OVERVIEW

The terms *ecological inference* and *ecological analysis* refer to any analysis based on data that are limited to characteristics of groups (aggregates) of individuals.^[1] Typically, these aggregates are geographically defined populations, such as counties, provinces, or countries. An enormous body of literature on ecological inference extends at least as far back as the early twentieth century. See, for example, Iversen^[2] and Achen and Shively^[3] for reviews of the social science literature, and Morgenstern^[4] for a review of the health sciences literature.

The objectives of ecological analyses may be roughly classified into two broad categories: *individual objectives*, which examine relations of group and individual characteristics to the outcomes of the individuals in the groups, and *purely contextual objectives*, to examine relations of group characteristics to group outcomes. A study may have both objectives. Most authors have focused on studies with only individual-level objectives and have emphasized the obstacles to *cross-level inference* from group-level (ecological) observations to individual-level relationships. This focus has led to a common misperception that individual-level relationships can be safely ignored if contextual objectives are the only interest. Several authors have also criticized the common practice of using strong (and sometimes implausible) modeling assumptions to generate cross-level inferences.^[2-5]

An overview of the literature surrounding these problems and the controversy they generate is given in "Ecological vs. Individual-Level Sources of Bias." The section "Multi-level Model Theory for Ecological Inference" provides some basic multi-level (hierarchical) structural-model

theory to define the problems (“structural” here means the underlying regression structure, apart from issues of random error or sampling variation). Further statistical theory, including fitting methods, can be found in Navidi et al.,^[6] Guthrie and Sheppard,^[7] Wakefield and Salway,^[8] Sheppard,^[9] and Wakefield.^[10] Multi-level studies that combine data from individual and ecological (aggregate) levels are discussed in “Multi-level Studies.” The section “Other Special Problems of Ecological Analysis” briefly describes other special problems of inference from ecological data and discusses some difficulties in causally interpreting the coefficients of contextual variables in multi-level models.

ECOLOGICAL VERSUS INDIVIDUAL-LEVEL SOURCES OF BIAS

Introduction

Studies limited to characteristics of aggregates are usually termed *ecological studies*.^[1,4,11–13] This term is perhaps unfortunate because the word *ecological* suggests that such studies are especially appropriate for examining the impact of environmental factors, including societal characteristics, and invites confusion between an ecological perspective (addressing relations at the environmental or social level) and an ecological study. As many authors have pointed out (Firebaugh,^[14] Von Korff et al.,^[15] Navidi et al.,^[6] Susser and Susser,^[16] Duncan et al.,^[17,18] Greenland^[5,19]), overcoming this confusion requires adopting a *multi-level* perspective, which allows theory and observations to be integrated on all levels: physiologic (exposures and responses of systems within individuals), individual (exposures and responses of individuals), and aggregate or contextual (exposures and responses of aggregates or clusters of individuals, such as locales or societies).

Defenders of ecological studies argue (correctly) that many critics have presumed individual-level relationships are the ultimate target of inference of all ecological studies, when this is not always so,^[16,20,21] and that contagious outcomes necessitate group-level considerations in modeling, regardless of the target level.^[22] They also point out that an ecological summary may have its own direct effects on individual risk, beyond that conferred by the contributing individual values. For example, the average economic status of an area can have effects on an individual over and above the effects of the individual's economic status.^[23,24] Unfortunately, some defenders make implicit assumptions to “prove” that entire classes of ecological studies are valid, or at least no less valid than individual-level analyses; see Refs.^[25–27] for critical commentaries against such arguments in the health sciences. Some ecological researchers are well aware of these problems and so explain their assumptions,^[28,29] but they still draw criticism because inferences are sensitive to those assumptions.^[30–32]

In the present article, I review some controversial assumptions in ecological analyses and then briefly discuss multi-level methods that represent individual-level and ecological data in a single model. Simple illustrations are used to make the points transparent to nonmathematical readers, problems of confounding and specification bias are highlighted, and an overview of the underlying mathematical theory is provided. Researchers have raised many other issues in the ongoing ecological study controversy; see the references for details, especially those in the “Other Special Problems of Ecological Analysis” section.

AGGREGATE-LEVEL CONFOUNDING DUE TO INDIVIDUAL-LEVEL EFFECTS

Two major types of measurements are used to describe aggregated data: summaries of distributions of individuals within the aggregates, such as mean age or percent female, and purely ecological (contextual) variables that are defined directly on the aggregate, such as whether there is a needle-exchange program in an area. The causal effects of the purely contextual variables are the focus of much social and epidemiological research.^[2,16,17,20,33] Nonetheless, most outcome variables of public health importance are summaries of individual-level distributions, such as prevalence, incidence, mortality, and life expectancy, all of which can be expressed in terms of average individual outcomes.^[34] Furthermore, many contextual variables are surrogates that summarize individual data; for example, neighborhood social class is often measured by average income and average education.

The use of summary measures in an ecological analysis introduces a major source of uncertainty in ecological inference. Summary measures depend on the joint individual-level distributions within aggregates, but distributional summaries do not fully determine (and sometimes do not seriously constrain) those joint distributions. This problem corresponds to the concept of “information lost to aggregation,” and is a key source of controversy about ecological studies.^[3]

The confounding of contextual and individual effects is illustrated in [Table 1](#). For simplicity, just two areas are used, but examples with many areas are available.^[25] Suppose we wish to assess a contextual effect, such as the impact of an ecological difference between areas A and B (such as a difference in laws or social programs) on the rate of a health outcome. We measure this effect by the amount RR_A that this difference multiplies the rate (the true effect of being in A vs. being in B). One potential risk factor, X , differs in distribution between the areas; an effect of X (measured by the rate ratio RR_X comparing $X = 1$ to $X = 0$ within areas) may be present, but we observe no difference in rates between the areas.

Do the ecological data in panel 1a of [Table 1](#) show no contextual effect? That is, do they correspond best with

Table 1 An Example Demonstrating the Confounding of Both Contextual and Individual Effects in Ecological Data

	Group A			Group B		
	X = 1	X = 0	Total	X = 1	X = 0	Total
<i>a. Ecological (marginal) data</i>						
Y = 1	?	?	560	?	?	560
N	60	40	100	40	60	100
Rate	?	?	5.6	?	?	5.6
<i>b. Possibility 1 ($RR_X = 2$, $RR_A = 7/8$)</i>						
Y = 1	420	140	560	320	240	560
N	60	40	100	40	60	100
Rate	7.0	3.5	5.6	8.0	4.0	5.6
<i>c. Possibility 2 ($RR_X = 1/2$, $RR_A = 8/7$)</i>						
Y = 1	240	320	560	140	420	560
N	60	40	100	40	60	100
Rate	4.0	8.0	5.6	3.5	7.0	5.6

The ecological data cannot identify the effect of group (A vs. B) on the rate of the outcome $Y = 1$ when only a marginal summary of the individual-level covariate X is available. Panels b and c show how within-group differences in outcome rates can affect inferences based on the ecological data in panel a. N = denominator (in thousands of person-years); RR_A and RR_X are the rate ratios for the true effects of A vs. B and of $X = 1$ vs. $X = 0$, respectively.

$RR_A = 1$? Unfortunately, the ecological (marginal) data on X distributions and the outcome rates are mathematically equally compatible with a broad spectrum of possibilities, two of which are given in panels 1b and 1c of Table 1. In the first possibility, area A has benefited from the contextual difference ($RR_A < 1$), but this fact has been obscured by area A’s higher prevalence of X , which is harmful ($RR_X > 1$). In the second possibility, area A has been harmed by the contextual difference ($RR_A > 1$), but this fact has been obscured by area A’s higher prevalence of X , which is beneficial ($RR_X < 1$). The correct answers in either possibility could be obtained by comparing the area rates after they have been standardized directly to a common X distribution; however, such standardization would require knowing the X -specific rates *within* the areas, which are not available in the example. Furthermore, an ecological regression could not solve the problem because it would only regress the crude area rates on the proportion with $X = 1$ in each area: Because both the crude area rates are 5.6, the ecological X -coefficient would be zero, hence the regression would produce no X -adjustment of the area rates.

Lacking within-area data on the joint distribution of X and the outcome, an ecological analysis must necessarily rely on external (prior) information to provide inferences about the contextual effect, although the margins may impose some bounds on the possibilities.^[3,28,35] If the X -specific rates in each area were assumed to be proportional to those in some external reference population with known X -specific rates, those external rates could be used to construct and compare standardized morbidity ratios for the areas (“indirect adjustment”). Unfortunately, such external rates are rarely available for all important covariates, and so other external (prior) information must be used to estimate the effect.

The results of such an analysis can be disappointing if the prior information is ambiguous. If X indicates, say, regular cigarette use, and the outcome is total mortality, we might be confident that RR_X is well above 1 and, hence, that the contextual effect (i.e., the A-B rate ratio) is protective. However, if X indicates regular alcohol consumption, we might feel justified in ruling out scenarios involving values for the rate ratio RR_X that are very far from 1. Nonetheless, because alcohol may be protective at moderate levels and causative at higher levels, we could not be sure of the direction of RR_X ; that would depend on the relative proportion of moderate and heavy drinkers in the areas. As a consequence, we could not be sure of the direction (let alone degree) of confounding in the ecological estimate of the contextual effect (i.e., the ecological A-B rate ratio of $5.6/5.6 = 1$).

The problem of cross-level confounding just illustrated has been discussed extensively since the early twentieth century (see Chapter 1 of Achen and Shively^[3]) and is a mathematically trivial consequence of the fact that marginals do not determine joint distributions. Yet this logical problem, which differentiates ecological from individual-level studies, continues to be misunderstood or ignored by many ecological researchers, so much that Achen and Shively^[3] remarked:

A cynic might conclude that social scientists tend to ignore logical problems and contradictions in their methods if they do not see anything to be done about them.

Their remark applies to the health sciences as well, as illustrated by this quote:

In practice, it may be that confounding usually poses a more intractable problem for ecological than for

individual-level studies. But this is due to the greater reliance on secondary data and proxy measures in ecological studies, *not to any problem inherent in ecological studies*.^[20][emphasis added]

Although ecological studies do suffer from greater reliance on secondary data and proxy measures, this passage is typical of defenses that overlook the aspects of confounding that *are* inherent in ecological studies. Other examples of such defenses are Cohen,^[36–38] Susser,^[39] and Pearce.^[21] A point illustrated in Table 1 is that, given confounding by a measured risk factor X , the individual-level data allow one to control the confounding in the most straightforward way possible: stratify on X . In contrast, confounding by X cannot be controlled by using only the ecological data, despite the fact that the effect under study is contextual (the effect of the social differences between areas A and B on outcome rates). Because contextual and individual effects are completely confounded in ecological data,^[5,14,19] the only solutions to this problem are to obtain individual data within the ecological units or to use assumptions that are untestable with the ecological data.^[3,25,26]

Another fallacy in some defenses of ecological studies is the claim that individual-level information is not needed if one is interested only in contextual (ecological) effects. Examples such as that in Table 1 show that such “holistic” arguments are incorrect, especially in health studies in which the outcome measure is an individual-level summary, because individual-level factors can confound the ecological results even if the study factor is contextual.^[5,14,19] Holistic arguments also tend to overlook the fact that ecological data usually refer to arbitrary administrative groupings, such as counties, that are often poor proxies for social context or environmental exposures,^[3] and that ecological relations can be extremely sensitive to the degree of grouping.^[40]

The problem illustrated in Table 1 also applies to ecological estimates of average individual-level effects (cross-level inferences from the ecological to the individual level).^[3,9,19] For example, if the illustration in Table 1 represented a contrast of two areas, A and B, with the goal of estimating the impact of differences in the X distribution, we would see very small contextual effects obscure substantial X effects in the ecological data.

To summarize, observational ecological data alone tell us little about either contextual or individual-level effects on summary measures of population health because they are compatible with a broad range of individual-level associations. Even if the overall goal is to estimate contextual effects, ecological manifestations of those effects (panel 1a of Table 1) can be confounded by individual-level relations and are not estimable without information about those relations. Thus methods that purport to adjust ecological results for the confounding problem just described either must employ external data about individual relations, or they must make assumptions about those relations. The

unobserved nature of the individual relations means that neither approach can be fully tested (validated) against the ecological data.

SOME ASSUMPTIONS AND FALLACIES IN ECOLOGICAL ANALYSES

All too often, identification is forced by making arbitrary modeling assumptions. Controversy then surrounds the credibility or strength of the assumptions used to derive effect estimates from ecological data, the sensitivity of those estimates to changes in assumptions, and failures of proposed methods in real or simulated data. For examples, compare Freedman et al.^[41] with their discussants; compare Greenland and Morgenstern,^[42,43] Richardson and Hemon,^[44] Greenland,^[45,46] Greenland and Robins,^[25,26] Piantadosi,^[47] Stidley and Samet,^[48] and Lagarde and Pershagen^[49,50] with Cohen;^[36–38,51] compare King^[28,29] with Rivers,^[30] Cho,^[52] Freedman et al.,^[31,32] and the example in Stoto;^[53] and compare Wen and Kramer^[54] with Naylor.^[27]

All causal inferences from observational epidemiological data must rely on restrictive assumptions about the distributions of errors and background causes. Most estimates also rely on parametric models for effects. Thus the validity of inferences depends on examining the sensitivity of the estimates to violations of the underlying assumptions and models.

RANDOMIZATION ASSUMPTIONS

Interpreting an association as a causal effect depends on some sort of no-confounding or ignorability assumption, which in statistical methodology becomes operationalized as a covariate-specific randomization assumption.^[55,56] Such causal inferences are usually sensitive to violations of those assumptions, and this sensitivity is a major source of controversy in most nonexperimental research.

Suppose we are to study K communities. The distinction between ecological and individual-level confounding may become clearer if we contrast two levels of randomized intervention to reduce sexually transmitted diseases (STDs):

- C) A community health program (e.g., establishment of free STD clinics) is provided at random to half of the communities (K is assumed to be even).
- W) Within community k , a treatment (e.g., a series of free STD-clinic visits) is randomly provided to a proportion p_k of individuals, and p_k varies across communities.

Trial C is a cluster-randomized design. In this trial, the ecological data would comprise a community treatment-status indicator plus the outcome measures

(e.g., subsequent STD rates). These data would support randomization-based inferences about what the average causal effect of the program would be for the K communities (the communities would be the analysis units, and the sample size for the inferences would be K). Nonetheless, analyzing the individual-level data from trial C as a K -stratum study (the usual individual-level analysis) would support no inferences at all about treatment effects because each stratum (community) would have a zero margin. Put another way, community and treatment effects would be completely confounded in the standard individual-level model. Analyzing the individual-level data would instead require methods for cluster-randomized trials.

In trial W, the ecological data consist of the proportion treated (p_k) in each community, along with outcome measures. Unless the p_k had been randomly assigned across communities (as in trial C, in which $p_k = 0$ or 1), the ecological data would *not* support randomization-based inferences about treatment effects. If the p_k were constant, there would be no data for such an analysis; if the p_k varied, the community and treatment effects would be confounded. (This observation is essentially a contrapositive version of Goodman's identification condition for ecological regression,^[57] translated to the present causal setting.) Nonetheless, the individual-level data from any of or all the communities with $0 < p_k < 1$ would support the usual randomization-based inferences (e.g., exact tests stratified on community). Taking X as the treatment indicator and $k = A, B$, the information in Table 1 can be used as an example of trial W with $p_A = 0.6$ and $p_B = 0.4$. The example then exhibits confounding of the ecological data with no confounding of the individual-level data within community.

To summarize, different randomization assumptions underlie causal inferences from individual-level and ecological studies; consequently, valid inferences from these two study types may require controlling for different (although possibly overlapping) sets of covariates.^[25]

OBSERVATIONAL STUDIES

Causal interpretations of associations in observational data have a fundamental weakness: The validity of such interpretations depends on the assumptions that natural or social circumstances have miraculously randomized the study exposure, for example, by carrying out trial C or W for us. The number of individuals in an individual-level study tells us nothing about the validity of this or other such "no-confounding" assumptions. Larger size only increases the precision of randomization-based inferences by reducing the chance that randomization left large imbalances of uncontrollable covariates across treatment groups. This benefit of size stems from, and depends on, an assumption of exposure randomization, as in trial W. Systematic (non-random) imbalances within groups by definition violate that assumption.

The same argument applies to ecological studies. The number of ecological groups involved tells us nothing about the validity of an assumption that the exposure distribution (p_k in the above binary-treatment trials) was randomized across the groups. The benefit of a large number of groups stems from and depends on the assumption that those distributions were randomized, as in trial C. Again, systematic imbalances across groups by definition violate that assumption. Despite these facts, some defenses of ecological studies have based on the circular argument that large numbers of areas would reduce the chance of ecological confounding;^[36] this circularity arises because the large-number effect assumes randomization across areas, which is precisely the assumption in doubt.

COVARIATE CONTROL

To achieve some plausibility in causal inferences from observational data, researchers attempt to "control" for covariates that affect the outcome but that are not affected by the exposure (potential confounders). In individual-level studies, the traditional means of control is to stratify the data on these covariates, because within such strata the exposed and unexposed units cannot have any imbalance on the covariates beyond the stratum boundaries; e.g., within a 65- to 74-year-old age stratum, the exposed and unexposed could not be more than 10 years apart in age. Causal inferences then proceed by assuming randomization *within* these strata. However implausible this assumption may be, in the face of observed imbalances it is always more plausible than the assumption of simple (unstratified) randomization.

Ecological data can be stratified, but with few exceptions, the ecological exposures and covariates in public-use databases are insufficient in detail and accuracy to create strata with assured balance on key covariates. For example, in ecological studies of radon levels and lung cancer rates across U.S. counties, the key covariates are the county-specific distributions of age, sex, race, and smoking habits. To address concerns about bias from possible relationships of these strong lung cancer risk factors to radon exposure, the county data would have to be stratified by age, sex, race, and smoking behavior (smoking behavior is multi-dimensional: it includes intensity, duration, and type of cigarette use). The relationship of radon distributions to lung cancer rates would then be examined across the stratum-specific county data. This stratified analysis requires the county-specific joint distributions of age, sex, race, smoking behavior and radon, and age, sex, race, smoking behavior, and lung cancer. Unfortunately, to date no such data have been available. Although data on the age-sex-race-lung cancer distributions in counties are published, their joint distributions with radon and smoking are unobserved. Only marginal distributions of radon are surveyed, and only crude summaries of cigarette sales are available.

The limitations of ecological stratification data may be better appreciated by considering an analogous problem in an individual-level study of residential radon and lung cancer. One might attempt to “control” for smoking by using cigarette sales in a subject’s county of residence as a surrogate for smoking behavior, as in Cohen.^[36] Presumably, few epidemiologists would regard this strategy as adequately controlling for smoking, especially considering that it would impute an identical “smoking” level to every subject in the county, regardless of age, sex, or lung cancer status. The shortcomings of this strategy arise precisely because smoking behavior varies greatly among individuals in a county, much more so than average smoking behavior varies across counties.^[25]

MODELING ASSUMPTIONS

To circumvent the inherent limitations of ecological studies, investigators have employed models in which ecological data (simple marginal summaries of crude exposure and covariate measures) are sufficient for causal inference. As mentioned earlier, these models are restrictive and are no more supported by ecological data than randomization assumptions. For example, a common assumption in ecological analyses is that effects follow a multiple-linear regression model. This assumption is both natural and somewhat misleading: A multiple-linear model for individual-level effects induces a multiple-linear ecological model, but this parallel relation between the individual and ecological regressions fails in the presence of non-additive or non-linear effects in the ecological groups.^[25,58–62]

Not even the functional form of individual-level effects (which can confound ecological associations, as in Table 1) is identified by the marginal data in ecological studies. For example, suppose individual risk R depends on the covariate vector X (which may contain contextual variables) via $R = f(X)$, and A indicates a context (such as geographic area). The ecological observations identify only relations of average risks $E_A(R)$ to average covariate levels $E_A(X)$ across contexts. These ecological relationships generally do not follow the same functional form as the individual relationships because $E_A(R) = E_A[f(X)] \neq f[E_A(X)]$, except in very special cases, chiefly those in which f is additive and linear in all the X components.

To prevent negative rate estimates, most analyses of individual-level epidemiological studies assume a multiplicative (log-linear) model for the regression of the outcome rate on exposure and analysis covariates, in which $f(X) = \exp(X\beta)$. Such non-linearities in individual regressions virtually guarantee that simple ecological models will be misspecified. These non-linearities further diminish the effectiveness of controlling ecological confounding, although the problem can be mitigated somewhat by expanding the ecological model to include more detailed

covariate summaries, if available,^[7,25] and by including higher-order covariate terms.^[44,59,62]

Unfortunately, some authors have denied the misspecification problem by claiming that a linear regression is justified by Taylor’s theorem.^[36] This justification is circular because approximate linearity of $f(X)$ over the within-context (area-specific) range of X is required for a first-order Taylor approximation of $f(X)$ to be accurate.^[25,60] Furthermore, in most applications, this requirement is known to be violated. For example, the dependence of risk on age is highly non-linear for nearly all cancers. Attempts to circumvent this non-linearity by using age-specific outcomes encounter a lack of age-context-specific measures of potential confounders, such as smoking. Using age-standardized rates also fails to solve the problem because it requires use of age-standardized measures of the covariates in the regression model (see “Other Special Problems of Ecological Analysis”), and such measures are rarely available.

MULTI-LEVEL MODEL THEORY FOR ECOLOGICAL INFERENCE

Most of the points discussed in this section are consequences of standard multi-level modeling theory.^[63] Suppose Y and X are an outcome (response) variate and a covariate vector defined on individuals, and R and Z are an outcome and covariate vector defined directly on aggregates (clusters); X may contain products among individual and aggregate covariates. For example, Y could be an indicator of being robbed within a given year; X could contain age, income, and other variables. With state as the aggregate, R could be the proportion robbed in the state over the year (which is just the average Y in the state), and Z could contain state average age and income and an indicator of whether hypodermic needles are available without prescription in the state.

Let μ_{ik} and x_{ik} be the expected outcome and X -value of individual i in aggregate k , with $\bar{\mu}_k$ and $\bar{x}_k$ their averages and z_k the Z -value for aggregate k , $k = 1, \dots, K$. One generalized-linear model (GLM) for individuals is

$$\mu_{ik} = f(\alpha + x_{ik}\beta + z_k\gamma) \quad (1)$$

If $R = \bar{Y}$, as when R is a rate, proportion, or average lifespan, model 1 induces the aggregate-outcome model

$$E_k(R) = \bar{\mu}_k = \frac{\sum_{i=1}^{N_k} f(\alpha + x_{ik}\beta + z_k\gamma)}{N_k} \quad (2)$$

where N_k is the size of aggregate k .^[61,64] If $\beta \neq 0$, $\bar{\mu}_k$ will depend on the within-aggregate X -distribution as well as on the individual-specific effects β and the contextual effects γ .

SPECIAL CASES

If the individual model is linear (so that $f(u) = u$), and if $Z = \bar{X}$, models 1 and 2 become

$$\mu_{ik} = \alpha + x_{ik}\beta + \bar{x}_k\gamma \quad (3)$$

And

$$\bar{\mu}_k = \alpha + \bar{x}_k(\beta + \gamma) \quad (4)$$

Model 4 exhibits the complete confounding of the individual effects β and the aggregate (contextual) effects γ in ecological data.^[14,23] Although the induced regression is linear and can be fit with ecological data, the identified coefficient $\beta + \gamma$ represents a blend of individual and contextual effects, rather than just contextual effects, as often supposed. To see this point, let Y again be a robbery indicator, let X be income (in thousands of dollars), and let k index states. Then β represents the difference in individual robbery risks associated with a \$1,000 increase in individual income X within a given state; γ represents the difference in individual robbery risks associated with a \$1000 increase in state-average income $\bar{X}$ among individuals of a given income X ; and $\beta + \gamma$ represents the unconditional difference in average state risk associated with a \$1,000 increase in average state income. In other words, β represents an *intrastate* association of personal income with personal robbery risk; γ represents an *interstate* association of average (contextual) state income with personal robbery risk within personal-income strata; and $\beta + \gamma$ represents an unconditional interstate association of average income with average risk, blending the conditional associations with robbery risk of personal and state-average income differences.

Linear models usually poorly represent risk and rate outcomes because of their failure to constrain predicted outcomes to nonnegative values. If we drop the linearity requirement but maintain $Z = \bar{X}$, model 1 can be rewritten

$$\mu_{ik} = f[\alpha + (x_{ik} - \bar{x}_k)\beta + \bar{x}_k(\beta + \gamma)] \quad (5)$$

showing that β may also be interpreted as the within-aggregate (intra-cluster) association of the transformed individual expected outcome $f^{-1}(\mu)$ with departures of X from the aggregate-specific average $\bar{X}$; $\beta + \gamma$ is then the complementary association of $\bar{X}$ with $\bar{\mu}$ across aggregates.^[9] The departure $X - \bar{X}$ is, however, a contrast of individual and contextual characteristics X and $\bar{X}$, rather than a purely individual characteristic X as in model 1, and $\beta + \gamma$ remains a mixture of individual and contextual effects.

Unfortunately, not even the mixed effect $\beta + \gamma$ can be estimated unbiasedly without further assumptions if the model is non-linear and if the only available covariates are aggregate means $\bar{X}$ and purely contextual variables. Richardson et al.^[59] and Dobson^[60] discussed assumptions

for unbiased ecological estimation of $\beta + \gamma$ under log-linear models, in which $f(u) = e^u$, although they implicitly assumed $\gamma = 0$ (no contextual effect) and so described them as assumptions for estimating β ; see also Sheppard,^[9] Prentice and Sheppard,^[61] Greenland,^[45] and Wakefield.^[65] From a scientific perspective these assumptions can appear highly artificial (e.g., X multivariate normal with constant covariance matrix across aggregates, which cannot be satisfied if X has discrete components that vary in distribution across aggregates), although the bias from their violation might not always be large.^[59,60,64] Nonetheless, even if the bias in estimating $\beta + \gamma$ is small, β and γ remain inseparable without further assumptions or individual-level data.

EXTENSIONS OF THE BASIC MODEL

Model 1 is a bi-level model, in that it incorporates covariates for individual-level characteristics (the X) and for one level of aggregation (the Z). The model can be extended to incorporate characteristics of multiple levels of aggregation.^[63] For example, the model could include a covariate vector Z_c of census-tract characteristics, such as the average income in the tract, and another vector Z_s of state characteristics, such as the law indicators and enforcement variables (e.g., conviction rates and average time served for various felonies). The above points can be roughly generalized by saying that the absence of data on one level should be expected to limit inferences about effects at other levels. The term *cross-level bias* denotes bias in coefficient estimates on one level that results from incorrect assumptions about effects on other levels (e.g., linearity or absence of effects); similarly, *cross-level confounding* denotes inseparability of different levels of effect, as illustrated above.

An important extension of multi-level models adds between-level covariate products (“interactions”) to model 1, thus allowing the individual effects β to vary across groups. Even with correct specification and multi-level data, the number of free parameters that results can be excessive for ordinary methods. One solution is to constrain the variation with hierarchical coefficient models, which induces a mixed model for individual outcomes.^[63] For example, adding products among X and Z to model 1 is a special case of replacing β by θ_k , with θ_k constrained by the second-stage model

$$\theta_k = \beta + A_k \delta \quad (6)$$

where A_k is a known fixed matrix function of z_k . The ensemble of estimates of the vectors $\theta_1, \dots, \theta_K$ can then be shrunk toward a common estimated mean $\bar{\beta}$ by specifying a mean-zero, variance τ^2 distribution for δ . This process is equivalent to (empirical) Bayesian averaging of model 1 with the expanded model:^[66]

$$\mu_{ik} = f(\alpha + x_{ik}\beta + z_k\gamma + x_{ik}A_k\delta) \quad (7)$$

Unfortunately, the nonidentifiability and confounding problems of ecological analysis only worsen in the presence of cross-level interactions.^[42]

ECOLOGICAL REGRESSION

Many, if not most, ecological researchers do not consider the individual or aggregated model 1 or 2 but instead directly model the aggregated outcome $\bar{Y}$ with an ecological regression model. If $Z = \bar{X}$, an ecological generalized linear model is

$$E_k(\bar{Y}) = \bar{\mu}_k = h(a + \bar{x}_k b) \quad (8)$$

With $h(u) = u$ and individual linearity (model 3), the results given above imply that b will be a linear combination of individual and contextual effects. Given individual non-linearities, model 8 will at best approximate a complex aggregate regression like model 2, and b will represent a correspondingly complex mixture of individual and contextual effects.^[9] These results also apply when purely contextual variables are included with $\bar{X}$ in Z and $\bar{x}_k$ is replaced by z_k in model 8.

The classic “ecological fallacy” (perhaps more accurately termed cross-level bias in estimating individual effects from ecological data) is to identify b in model 8 with β in model 1. This identification is fallacious because unless $\gamma = 0$ (contextual effects absent), even linearity does not guarantee $b = \beta$. With individual-level non-linearity, even $\gamma = 0$ does not guarantee $b = \beta$. Ecological researchers interested in estimating contextual effects should note the symmetrical results that apply when estimating contextual effects from ecological data. Even with linearity, $b = \gamma$ will require $\beta = 0$, which corresponds to no individual-level effects of X , even when the aggregate summaries of X in Z (such as $\bar{X}$) have effects. In other words, for the ecological coefficient b to correspond to the contextual effect γ , any within-group heterogeneity in individual outcomes must be unrelated to the individual analogues of the contextual covariates. For example, if X is income and Z is mean income $\bar{X}$, $b = \gamma \neq 0$ would require individual incomes to have no effect except as mediated through average area income. Such a condition is rarely, if ever, plausible.

MULTI-LEVEL STUDIES

Problems arising from within-group heterogeneity should diminish as the aggregates are made more homogeneous on relevant covariates. Heterogeneity of social factors may also decline as the aggregates become more restricted (e.g., census tracts tend to be more homogeneous on income and education than counties). Nonetheless, the benefits of such restriction may be nullified if important covariate measures (e.g., alcohol and tobacco) are available only for the

broader aggregates, because confounding by those covariates may remain uncontrollable.

Suppose, however, that within-region, individual-level survey data are available for those covariates. Individual-level risk models may then be applied to within-region survey data and the resulting individual risk estimates aggregated for comparison to observed ecological rates.^[60,67] For example, suppose we have a covariate vector X measured on N_k surveyed individuals in region k , a rate model $r(x; \beta)$ with a β estimate $\hat{\beta}$ from individual-level studies (e.g., a proportional-hazards model derived from cohort-study data), and the observed rate $\bar{r}_k$ in region k . We may compare $\bar{r}_k$ to the area rate predicted from the model applied to the survey data, $\Sigma_i r(x_i; \hat{\beta}) / N_k$, where the sum is over the surveyed individuals $i = 1, \dots, N_k$ and x_i is the value of X for survey individual i . This approach is a regression analogue of indirect adjustment: $\hat{\beta}$ is the external information and corresponds to the reference rates used to construct expectations in standardized morbidity ratios.

Unfortunately, fitted models that generalize to the regions of interest are rarely available. Thus, starting from the individual-level model $r_k(x; \beta) = r_{0k} \exp(x\beta)$, Prentice and Sheppard^[61] and Sheppard and Prentice^[64] proposed estimating the individual parameters β by directly regressing the $\bar{r}_k$ on the survey data using the induced aggregate model $r_k = r_{0k} E_k[\exp(x\beta)]$, where $E_k[\exp(x\beta)]$ is the average of $\exp(x\beta)$ over the individuals in region k . Sheppard and Prentice^[64] showed how the observed rates $\bar{r}_k$ and the survey data (the x_i) can be used to fit this model. As with earlier methods, their method estimates region-specific averages from sample averages, but in the absence of external data on β , it constrains the region-specific baseline rates r_{0k} (e.g., by treating them as random effects); see Cleave et al.^[12] and Wakefield^[10] for related approaches.

Prentice and Sheppard^[61] called their method an “aggregate-data study”; however, much of the social science literature has long used this term as a synonym for “ecological study,”^[14,33] and so I would instead call it an incomplete multi-level study (“incomplete” because, unlike a complete multi-level study, individual-level outcomes are not obtained). Prentice and Sheppard^[61] conceived their approach in the context of cancer research, in which few cases would be found in modestly sized survey samples. For studies of common acute outcomes, Navidi et al.^[6] proposed a complete multi-level strategy in which the within-region surveys obtain outcome as well as covariate data on individuals, which obviates the need for identifying constraints.

Multi-level studies can combine the advantages of both individual-level and ecological studies, including the confounder control achievable in individual-level studies and the exposure variation and rapid conduct achievable in ecological studies.^[7] These advantages are subject to many assumptions that must be carefully evaluated.^[61,65] Multi-level studies share several of these assumptions with ecological studies. For example, multi-level studies based on

recent individual surveys must assume stability of exposure and covariate distributions over time to ensure that the survey distributions are representative of the distributions that determined the observed ecological rates. This assumption will be suspect when individual behavioral trends or important degrees of migration emerge after the exposure period relevant to the observed rates.^[68,69] Multi-level studies can also suffer from the problem, mentioned earlier, that the aggregate-level (ecological) data usually concern arbitrary administrative or political units, and so can be poor contextual measures. Furthermore, multi-level studies face a major practical limitation in requiring data from representative samples of individuals within ecological units, which can be many times more expensive to obtain than the routinely collected data on which most ecological studies are based.

In the absence of valid individual-level data, multi-level analysis can still be applied to the ecological data via non-identified random-coefficient regression. As in applications to individual-level studies,^[70] this approach begins with specifying a hierarchical prior distribution for parameters not identified by available data. The distribution for the effect of interest is then updated by conditioning on the available data. This approach is a multi-level extension of random-effects ecological regression to allow constraints on β (including a distribution for β) in the aggregate model, in addition to constraints on the r_{0k} . It is essential to recognize that these constraints are what identify exposure effects in ecological data; hence, as with all ecological results, a precise estimate should be attributed to the constraints that produced the precision.

OTHER SPECIAL PROBLEMS OF ECOLOGICAL ANALYSIS

Thus far, I have focused on problems of confounding and cross-level effects in ecological studies. These are not the only problems of ecological studies. Several others are especially noteworthy for their divergence from individual-level study problems or their absence from typical individual-level studies.

NON-COMPARABILITY AMONG ECOLOGICAL ANALYSIS VARIABLES

The use of non-comparably standardized or restricted covariates in an ecological model such as model (8) can lead to considerable bias.^[45,71] Typically, this bias occurs when $\bar{Y}$ is age-standardized and specific to sex and race categories but $\bar{X}$ is not. For example, disease rates are routinely published in age-standardized, sex-race-specific form, but most summary covariates (e.g., alcohol and tobacco sales) are not. Such non-comparability can lead to bias in the ecological coefficient b in model 8 as a representation of

the mixed effect $\beta + \gamma$, because the coefficients of crude covariate summaries will not capture the rate variation associated with variation in alcohol and tobacco use by age, sex, and race.

Unfortunately, non-comparable restriction and standardization of variables remain common in ecological analyses. Typical examples involve restricted standardized rates regressed on crude ecological variables, such as sex-race-specific, age-standardized mortality rates regressed on contextual variables (e.g., air-pollution levels) and unrestricted unstandardized summaries (e.g., per capita cigarette sales). If, as is usual, only unrestricted, unstandardized regressor summaries are available, less bias might be incurred by using the *crude* (rather than the standardized) rates as the outcome and controlling for ecological demographic differences by entering multiple age-sex-race-distribution summaries in the regression^[71] (e.g., proportions in different age-sex-race categories). More work is needed to develop methods for coping with non-comparability.

MEASUREMENT ERROR

The effects of measurement error on ecological and individual-level analyses can be quite different. For example, Brenner et al.^[72] found that independent non-differential misclassification of a binary exposure could produce bias away from the null and even reverse estimates from a standard linear or log-linear ecological regression analysis, although the same error would produce only bias toward the null in a standard individual-level analysis. Analogous results were obtained by Carroll^[73] for ecological probit regression with a continuous measure of exposure. Results of Brenner et al.^[72] also indicate that ecological regression estimates can be extraordinarily sensitive to errors in exposure measurement. On the other hand, Brenner et al.^[74] found that independent non-differential misclassification of a single binary confounder produced no increase in bias in an ecological linear regression. Similarly, Prentice and Sheppard^[61] and Sheppard and Prentice^[64] found robustness of their incomplete multi-level analysis to purely random measurement errors.

Besides assuming very simple models for individual-level errors, the foregoing results assume that the ecological covariates in the analysis are direct summaries of the individual measures. Often, however, the ecological covariates are subject to errors beyond random survey error or individual-level measurement errors, for example, when per capita sales data are used as a proxy for average individual consumption, and when area measurements such as pollution levels are subject to errors. Some researchers have examined the impact of such *ecological* measurement error on cross-level inferences under simple error models,^[6,8,75] but more research is needed, especially for the situation in which the grouping variable is

an arbitrary administrative unit serving as a proxy for a contextual variable.

PROBLEMS IN CAUSAL INTERPRETATION

The present article, like most of the literature, has been rather loose in using the word *effect*. Strictly speaking, the models and results discussed here apply only to interpretations of coefficients as measures of conditional associations. Their interpretation as measures of causal effects in formal causal models such as potential-outcome (counterfactual) models^[76–79] raises some problems not ordinarily encountered in individual-level modeling.

To avoid technical details, consider the linear-model example. A causal interpretation of β in model 3 is that it represents the change in an individual's risk that would result from increasing that person's income by \$1,000. Apart from the ambiguity of this intervention (does the money come from a pay raise or direct payment?), one might note that it would also raise the average income value $\bar{X}_k$ by $\$1,000/N_k$ and produce an additional change of γ/N_k in the risk of the individual. This interpretation apparently contradicts the original interpretation of β as *the* change in risk, from whence we see that β must be interpreted carefully as the change in risk given that average income is (somehow) held constant, for example, by reducing everyone else's income by $\$1,000/(N_k - 1)$ each.

If the size of the aggregate N_k is large, this problem is trivial; if it is small, however (e.g., the aggregate is a census tract), it may be important. One solution with a scientific basis is to recognize $\bar{X}$ as a contextual surrogate for socio-economic environment, in which case the contextual value $\bar{X}_k$ in model 1 might be better replaced by an individual-level variable $\bar{X}_{(-i)k}$, the average income of persons in aggregate k apart from individual i . Note that the mean of $\bar{X}_{(-i)k}$ is $\bar{X}_k$, and so its effect could not be separated from that of personal income when only aggregate means are available; that is, β and γ remain completely confounded.

Causal interpretation of the contextual coefficient γ is symmetrically problematic. This coefficient represents the change in risk from a \$1,000 increase in average income $\bar{X}_k$, while keeping the person's income x_{ik} the same. This income can be kept constant in many ways, for example, by giving everyone but person i a $\$1,000N_k/(N_k - 1)$ raise, or by giving one person other than i a $\$1,000N_k$ raise. The difference between these two interventions is profound and might be resolved by clarifying the variable for which $\bar{X}$ is a surrogate. Similar comments apply to causal interpretation of b in the ecological model (model 8).

Problems of causal interpretation only add to the difficulties in the analysis of contextual causal effects, but, unlike confounding, they may be as challenging for individual-level and multi-level studies as they are for ecological studies.^[2] Addressing these problems demands that detailed subject-matter considerations be used to construct

explicit multi-level causal models in which key variables at any level may be latent (not directly measured).

PROBLEMS IN AGGREGATION LEVEL

Another serious and often overlooked conceptual problem involves the special artificiality of typical model specifications above the individual level. Ecological units are usually arbitrary administrative groupings, such as counties, which may have only weak relations to contextual variables of scientific interest, such as social environment.^[3] Compounding this problem is the potentially high sensitivity of aggregate-level relationships to the grouping definitions.^[40] In light of these problems, it may be more realistic to begin with at least a tri-level specification, in which one aggregate level is of direct scientific interest (e.g., neighborhood or community) and the other (or others) are the aggregates for which data are available (e.g., census tracts or counties). This larger initial specification would at least clarify the proxy-variable (measurement surrogate) issues inherent in most studies of contextual effects.

CONCLUSION

The validity of any inference can only benefit from critical scrutiny of the assumptions on which it is based. Users of surveillance data should be alert to the special assumptions needed to estimate an effect from ecological data alone, and to the profound sensitivity of inferences to those assumptions (even if the estimate is of a contextual effect). The fact that individual-level studies have complementary limitations does not excuse the failure to consider these assumptions.

Nonetheless, ecological data are worth examining. Their value has been demonstrated by careful ecological analyses^[59,80] and by methods that combine individual and ecological data.^[6,18,61,64,65,81–83] Furthermore, the *possibility* of bias does not prove the presence of bias, and a conflict between ecological and individual-level estimates does not by itself mean that the ecological estimates are the more biased.^[20,25,26] The two types of estimates share some biases but not others, making it possible for the individual-level estimates to be the more biased.

The effects measured by the two types of estimates may differ as well; ecological estimates incorporate a contextual component that is absent from the individual estimates derived from a narrow context. Indeed, the contextual component may be viewed as both a key strength and weakness of ecological studies, because it is often of greatest importance, although it is especially vulnerable to confounding. Thus, in the absence of good multi-level studies, ecological studies will no doubt continue to fuel controversy and so inspire the conduct of potentially more informative studies.

Abstract

The investigator may be interested in the dose that results in a specified level of response, typically 50% or 90%. Such doses are referred to as effective doses. This entry addresses several research and statistical models to further break down ED₅₀ and ED₉₀ results.

INTRODUCTION

Data in which each observation assumes only one of two possible outcomes are called binary. This type of data arises in many situations. One area where binary data are frequently observed is biological assay. Much has been written about the toxicity of drugs and their relative effectiveness when compared with each other.^[1,2] Typically, test subjects are given specified doses of a drug and one observes whether they respond or not. Interest is often focused on understanding the relationship between the probability that the subject responds and the dose administered to the subject.

OVERVIEW

The investigator may be interested in the dose that results in a specified level of response, typically 50% or 90%. Such doses are referred to as effective doses. An important quantity of interest in biological assays is the value of x such that $p(x) = 0.5$; that is, experiments are frequently summarized by an estimate of the median effective dose (ED₅₀), namely that dose that causes 50% of the subjects to respond. (See Refs. [3,4] for a discussion of the pros and cons of the usage of the ED₅₀ and further literature about it.)

As an illustration, Table 1 is the data set supplied to Abdelbasit and Plackett^[5] by P. S. Hewlett, upon which Sitter and Wu^[6] based their configurations. The maximum likelihood (ML) fit of the logistic and probit models (see below for details) to the data and estimated ED₅₀ are displayed in Fig. 1.

In this paper, in addition to the ED₅₀, the estimation of a more extreme percentage point will be of interest. The 90% effective dose (ED₉₀) is specifically considered. The ED₅₀ has been a crucially important summary measure in bioassay for many years. The ED₉₀ is probably the typical “extreme” dose studied when one is interested in extreme doses rather than the median effective dose. A large

literature^[6–14] has considered the coverage probabilities of various methods of interval estimation of the ED₅₀, assuming a logistic dose–response curve. Engeman et al.^[15] and Robertson et al.^[16] investigated the properties of several traditional analytical procedures for estimating the 90% lethal dose (LD₉₀), including the percentage coverage of the LD₉₀ by nominal 95% confidence intervals. Two of the procedures considered were maximum likelihood estimation and minimum chi-squared estimation, under the assumption of a logistic model. However, little attention has been paid to what happens to the performance of these estimators if the assumption of a logistic dose–response curve is incorrect. It is important to consider this eventually, as the dose–response relationship is usually unknown; thus we are usually never certain that what we assume is actually correct.

We focus our interest on the performance of four interval estimation methods of the ED₅₀/ED₉₀, derived from incorrectly assuming a logistic dose–response curve when an alternative dose–response model is actually true, and address the question of their robustness. Three alternative models are considered, these being a probit dose–response curve, a cubic logistic dose–response curve,^[17] and an asymmetric Aranda–Ordaz dose–response curve.^[18] The four methods of interval estimation of the ED₅₀/ED₉₀ considered here are Fieller’s (F) method,^[1,6] the likelihood ratio (LR) method,^[7,20] the Bartlett adjusted likelihood ratio (BLR) method,^[10,19] and the score test (ST) method.^[10,20] In the third section of this paper, a statistical model for binary response data is introduced to compare the performance of interval estimation methods. The four methods of interval estimation of the ED₅₀/ED₉₀ are briefly outlined in the fourth section. The numerical simulation experiments are briefly discussed in the fifth section. The distribution functions used for the true underlying dose–response relationship are described and the results of these experiments are presented in the sixth section. Finally, we conclude the paper with some discussions with regard to, in particular, the robustness of the four methods under model misspecification.

STATISTICAL MODEL

An observation at dose level x_i is classified as a response or nonresponse with respective probabilities p_i and $1 - p_i$. We consider the design problem where the statistician must choose a set of levels $\mathbf{x} = (x_1, \dots, x_k)$ and the number of independent observations $\mathbf{n} = (n_1, \dots, n_k)$ to take at these levels, subject to a fixed total $n = \sum_{i=1}^k n_i$, to make some inference on the basis of the observed frequencies of a response $\mathbf{r} = (r_1, \dots, r_k)$. The appropriate assumption would be to view $r_1, \dots, r_k$ as being mutually independent binomial (n_i, p_i) random variables with

$$\text{logit}(p_i) = \alpha + \beta x_i, \quad i = 1, \dots, k \quad (1)$$

The ED _{ν} ($\nu = 50, 90$) is then given by

$$\mu_\nu = (c_\nu - \alpha)/\beta \quad (2)$$

where $c_\nu = \ln[\nu/(100 - \nu)]$. In particular, $\mu_{50} = -\alpha/\beta$ and $\mu_{90} = (\ln 9 - \alpha)/\beta$. Our log-likelihood function is

$$L = \sum_{i=1}^k [r_i \log p_i + (n_i - r_i) \log(1 - p_i)] \quad (3)$$

The maximum likelihood estimator (MLE) of μ_ν is $\hat{\mu}_\nu = (c_\nu - \hat{\alpha})/\hat{\beta}$ (i.e. $\hat{\mu}_{50} = -\hat{\alpha}/\hat{\beta}$) and $\hat{\mu}_{90} = (\ln 9 - \hat{\alpha})/\hat{\beta}$, with $\hat{\alpha}$ and $\hat{\beta}$ denoting the respective MLEs of α and β .

When a model such as the logistic model is fitted to binary assay data, the model may be used to summarize the data, through the model parameters, and in addition the model may form the basis for comparison between different sets of data. In many cases, a binary response experiment is used to estimate the dose level x_i that will cause a particular response in 100 p_i % of the subjects to which it is administered. A commonly used summary of a fitted model is the ED₅₀. By itself, a point estimate of the ED₅₀ is generally viewed as being insufficient;^[4] a better summary usually requires the calculation of an interval estimate. Assuming a parametric model for the dose-response

Table 1 Toxicity of Oil to *Sitophilus granarius*

Log (dose) (x_i)	Number of subjects (n_i)	Number affected (r_i)	Observed proportion (p_i)
0.2810	47	47	1.00
0.2304	50	50	1.00
0.1523	50	50	1.00
0.0864	50	46	0.92

-0.1487	50	2	0.04
-0.2147	50	1	0.02
-0.3098	50	0	0.00

Fig. 1 The ML fit of the models to the data and estimated ED₅₀

relationship, several methods can be used to construct the confidence intervals for the ED ν ($\nu = 50, 90$).

THE FOUR METHODS OF INTERVAL ESTIMATION

The 95% Fieller interval for μ_ν is given by the set of $\mu_{\nu 0}$ satisfying

$$(\hat{\alpha} - c_\nu + \mu_{\nu 0} \hat{\beta})^2 (v_{11} + 2\mu_{\nu 0} v_{12} + \mu_{\nu 0}^2 v_{22})^{-1} < z_{0.05}^2 \quad (4)$$

where $V = (v_{ij})$ is the estimated asymptotic variance matrix of $(\hat{\alpha}, \hat{\beta})^T$, v_{11} and v_{22} are the estimated asymptotic variances, $\text{var}(\hat{\alpha})$ and $\text{var}(\hat{\beta})$, v_{12} is the estimated asymptotic covariance $\text{cov}(\hat{\alpha}, \hat{\beta})$, and $z_{0.05}^2$ is the upper 0.05 point of χ^2 with one degree of freedom (χ^2_1).

Suppose that under $H_0: \mu_\nu = \mu_{\nu 0}$, β is estimated, subject to $\mu_{\nu 0}$ by maximum likelihood and the value of the log-likelihood, $L_{H_0}(\mu_{\nu 0})$, is obtained. Under $H_1: \mu_\nu \neq \mu_{\nu 0}$, the overall maximum of the log-likelihood, maximized with respect to β and μ_ν , is L_{H_1} . Thus the 95% LR interval for μ_ν is given by the set of $\mu_{\nu 0}$ satisfying $\Gamma(\mu_{\nu 0}) < z_{0.05}^2$, where $\Gamma(\mu_{\nu 0}) = -2\{L_{H_0}(\mu_{\nu 0}) - L_{H_1}\} = D(\mu_{\nu 0}) - D(\hat{\mu}_\nu)$ is the deviance under the null hypothesis H_0 minus the deviance under the alternative hypothesis H_1 .

The Bartlett adjusted likelihood ratio test takes the form

$$\text{BLR} = \Gamma(\mu_{\nu 0})/\tilde{M} \quad (5)$$

Here M is the Bartlett factor, with the tilde denoting evaluation under $H_0: \mu_\nu = \mu_{\nu 0}$. The BLR statistic has an asymptotic χ^2_1 distribution under H_0 . As with the LR test itself, a 100(1- α)% BLR interval for μ_ν is the set of values $\mu_{\nu 0}$ not rejected by the test, namely those satisfying $\text{BLR} < z_{0.05}^2$. Explicitly, the Bartlett factor can be written as

$$M = 1 + (\varepsilon_2 - \varepsilon_1) \quad (6)$$

where

$$\varepsilon_2 = \text{tr}(\mathbf{H}\mathbf{Z}_d^2)/4 + \mathbf{1}_k^T \mathbf{F}(2\mathbf{Z}^{(3)} + 3\mathbf{Z}_d \mathbf{Z}_d) \mathbf{F} \mathbf{1}_k / 12 \quad (7)$$

and

$$\varepsilon_1 = \mathbf{1}_k^T \mathbf{H} \mathbf{x}^{(4)} / 4 (\mathbf{x}^T \mathbf{V} \mathbf{x})^2 + 5 (\mathbf{1}_k^T \mathbf{F} \mathbf{x}^{(3)})^2 / 12 (\mathbf{x}^T \mathbf{V} \mathbf{x})^3 \quad (8)$$

where the $k \times k$ matrices $\mathbf{F}$, $\mathbf{H}$, $\mathbf{V}$, and $\mathbf{Z}$ are given respectively by $\mathbf{F} = \mathbf{V}(\mathbf{I}_k - 2\mathbf{p})$, $\mathbf{H} = \mathbf{V}(6\mathbf{V}\mathbf{n}^{-1} - \mathbf{I}_k)$, $\mathbf{V} = \text{diag}\{n_i p_i (1 - p_i)\}$, and $\mathbf{Z} = \mathbf{X}(\mathbf{X}^T \mathbf{V} \mathbf{X})^{-1} \mathbf{X}^T$, $\mathbf{Z}_d$ is a diagonal matrix composed of the diagonal elements of $\mathbf{Z}$. Here $\mathbf{p} = \text{diag}(p_i)$, $\mathbf{n}^{-1} = \text{diag}(n_i^{-1})$, $\mathbf{x} = (x_1 - \mu_{v0}, \dots, x_k - \mu_{v0})^T$, $\mathbf{I}_k$ is a $k \times k$ identity matrix, $\mathbf{X}$ is the matrix with first column $\mathbf{1}_k$, $\mathbf{1}_k = (1, \dots, 1)^T$ of length k and second column the vector $(x_1, \dots, x_k)^T$. A superscript ($q = 3$ or 4) in brackets denotes the q th Hadamard product.^[10,19]

The score test under the null hypothesis $H_0: \mu_v = \mu_{v0}$ is given by

$$S = \frac{\sum_{i=1}^k \hat{w}_{i0} (x_i - \mu_{v0})^2 \left[\sum_{i=1}^k (r_i - n_i \hat{p}_{i0}) \right]^2}{\sum_{i=1}^k \hat{w}_{i0} \sum_{i=1}^k \hat{w}_{i0} (x_i - \bar{x}_{v0})^2} \quad (9)$$

where $\bar{x}_{v0} = \sum_{i=1}^k \hat{w}_{i0} x_i / \sum_{i=1}^k \hat{w}_{i0}$, $\hat{w}_{i0} = n_i \hat{p}_{i0} (1 - \hat{p}_{i0})$ with the circumflex denoting evaluation under $H_0: \mu_v = \mu_{v0}$. Under H_0 , S has, asymptotically, χ_1^2 distribution. Again, the confidence interval for μ_v is the set of values μ_{v0} not rejected by the test.

NUMERICAL EXPERIMENTS

The sets of experimental configurations used to compare the four methods of interval estimation of the ED $_{\nu}$ ($\nu = 50, 90$) are summarized in Table 2. Data sets (a) and (b) are based on configurations reported by William,^[7]

who referred to conducting experiments with a total of 20–30 subjects at four to six dose levels, and data set (c) is that reported by Sitter and Wu.^[6] data set (c) contains a number of extreme responses. These configurations are used to compare the four methods of interval estimation for the ED₅₀. The remaining three sets of configurations are used in the equivalent study for the ED₉₀. Data set (d) is based on the configurations with the six dose levels described by Engeman et al.,^[15] namely, equally spaced doses on a geometric scale with the theoretical levels of response for the first and last doses set at 0.05 and 0.95, respectively. Based on these response probabilities with $(\beta, \mu_{90}) = (1, 7.2)$, we calculated dose levels $x_1, \dots, x_6$. Data sets (e) and (f) reported by Robertson et al.^[16] corresponded to response probabilities $p_i = 0.2, 0.3, 0.4, 0.45, 0.55, 0.6, 0.7, 0.8$ and $p_i = 0.1, 0.15, 0.7, 0.75, 0.8, 0.85, 0.9, 0.95$, respectively. Based on these response probabilities, we calculated dose levels presented in Table 2 corresponding to a logistic distribution with $\beta = 1$ and first dose level $x_1 = 0$. The choices of $(\beta_1, \mu_{90}) = (1, 3.5)$ and $(1, 4.4)$ in data sets (e) and (f), respectively, approximately correspond to the probabilities used by Robertson et al. All of the experiments were conducted with an equal number of observations per dose, so that $n_i = n/k$.

When the cubic logistic model was the true dose–response model, the values of γ chosen were $\gamma = 0, 0.05, 0.1, 0.15$, and 0.2 in data sets (a) and (b) and $\gamma = 0, 1, 2, 5$, and 10 in data set (c) for the ED₅₀, and $\gamma = 0, 0.001, 0.005, 0.01$, and 0.02 for the ED₉₀. When the asymmetric Aranda–Ordaz model was the true dose–response model, the values of λ used were $\lambda = 0.8, 0.9, 1, 1.1$, and 1.2 for both the ED₅₀ and the ED₉₀. The reason for using these values of γ or λ is to ensure that the data are generated from realistic dose–response curves.

The Genstat package^[21] was used to obtain estimated coverage probabilities (CP) corresponding to nominal 95% confidence intervals for each of the four types of intervals. For each of the experiments, 10,000 simulated data sets

Table 2 Sample Sizes (n_i), β , μ_v , and the Values of the Dose Levels (x_i) for the Six Sets of Experimental Configurations Investigated

1. Experimental configurations for the ED ₅₀				
Set	n_i	β	μ_{50}	Doses (x_i)
(a)	6	1, 2	3, 3.5, 4	1, 2, ..., 5
(b)	5	1, 2	3.5, 4, 4.5	1, 2, ..., 6
(c)	10, 20, 30, 50	7, 14	0.1, 0.2, 0.3	−0.3098, −0.2147, −0.1487, −0.0809, −0.0362, 0.0864, 0.1523, 0.2304, 0.2810
2. Experimental configurations for the ED ₉₀				
Set	n_i	β	μ_{90}	Doses (x_i)
(d)	30, 50, 70, 90	1, 2	7.1, 7.2, 7.3	2.056, 3.233, 4.411, 5.589, 6.767, 7.944
(e)	8, 15, 30, 60	1, 2	3.3, 3.5, 3.7	0.000, 0.539, 0.981, 1.186, 1.587, 1.792, 2.234, 2.773
(f)	8, 15, 30, 60	1, 2	4.2, 4.4, 4.6	0.000, 0.463, 3.045, 3.296, 3.584, 3.932, 4.394, 5.142

were generated. In the simulation study, our data are generated from the three true dose–response curves, but we (mistakenly) regard the data as having arisen from a logistic dose–response curve.

It is also useful to determine whether the extended model is actually a better fit to the data than the simpler logistic model. We could use a likelihood ratio test or score test to determine this. The score test is more convenient, as it only requires the logistic model to be fitted, whereas the likelihood ratio test requires fitting of the extended model as well, and this is somewhat more difficult. Thus the score test is used here. Data sets for which the score tests were significant at the 5% level of significance were excluded from the calculation of the coverage probabilities. This was performed to mimic actual data analysis in which one would expect the inappropriateness of the assumed model to be detected if the model fit was sufficiently bad. The results obtained for the cubic–logistic and asymmetric Aranda–Ordaz distributions are thus based on data sets for which a diagnostic test statistic has not found real evidence of the inadequacy of the assumed logistic model. The performance of these score tests is critical and may have a potential bearing on the final results. Here the effect of the extra parameter is taken into consideration, as it appears in the expression of μ_v for the true model and affects those data sets for which the score test is not rejected. It is this μ_v value for the extended model, not μ_v for the logistic model, for which the 95% confidence interval is appropriate.

In addition, excluded are intervals for data sets for which the null hypothesis $\beta = 0$ could not be rejected against the alternative hypothesis $\beta \neq 0$ at the 5% level of significance, using the Wald test.^[6] Also, to confine ourselves to cases in which the MLEs are calculable for all of the methods, data sets with either zero partial responses or one partial response were excluded from our analysis;^[6,22] in addition, the score tests for the extra parameter of the cubic logistic and asymmetric Aranda–Ordaz families cannot be determined if there are either zero partial responses or one partial response.

SIMULATION RESULTS

First, we describe the three models that were used to represent the true dose–response relationships in the simulation experiments outlined in “Numerical Experiments.”

The first distribution used to represent the true dose–response relationship was the normal distribution function

$$p(x_i) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\rho(x_i)} \exp(-z^2/2) dz \quad (10)$$

where $\rho(x_i) = (\sqrt{3}/\pi)(\alpha + \beta x_i)$ and our probit model has been parameterized to have the same variance as the logistic model^[3] for a more detailed discussion of this point.

The second distribution used was the cubic logistic distribution function.^[17]

$$p(x_i) = 1/\left\{1 + \exp\left[-\left(\beta(x_i - \mu_{50}) + \gamma(x_i - \mu_{50})^3\right)\right]\right\} \quad (11)$$

This is a symmetric distribution function that contains the logistic distribution function as a special case when $\gamma = 0$. Note that when $\gamma < 0$, $p(x)$ is not a monotonic function of x although it may be monotonic over the observed range. As a consequence, extreme doses either do not exist or are not unique if $\gamma < 0$. Therefore it is concluded that the model is most useful when $\gamma \geq 0$.^[17]

The third distribution used was the asymmetric Aranda–Ordaz distribution.^[18]

$$p(x_i) = \begin{cases} 1 - [1 + \lambda \exp(\alpha + \beta x_i)]^{-1/\lambda} & \lambda \exp(\alpha + \beta x_i) > -1 \\ 0 & \text{otherwise} \end{cases} \quad (12)$$

This is an asymmetric distribution function that contains the logistic distribution function as a special case when $\lambda = 1$.

For the three true dose–response curves, we define a particular method of interval estimation as being “robust” if the CP is within the range $\omega = \{X: |X| \leq 0.5\}$. Here $X = \text{CP} - 95$ and CP is the estimated percentage coverage probability corresponding to a nominal 95% confidence interval, obtained via the fitting of a logistic model—whether or not this is the appropriate model. Values of X close to zero indicate that a method of interval estimation is achieving an observed level of coverage close to its nominal level.

From this definition, we consider that a method of interval estimation is liberal when $X < -0.5$ and conservative when $X > 0.5$, respectively. Here the range of $|X| \leq 0.5$ was chosen because of it being approximately equal to the range of values for which an approximate 95% confidence interval (for the CP) would cover 95%.

Robustness of Interval Estimators of the ED₅₀

The Probit Model

For the experimental configurations in data sets (a) and (b), the simulation results shown in Fig. 2 indicate that the Fieller method of interval estimation is always conservative. There are a number of liberal results that occur for the LR, BLR, and score test methods. The Fieller method displays no robust results; the LR method has only one robust result; and the BLR and score test methods each have four robust results from the 12 obtained.

The simulation results shown in Fig. 2, based on data set (c), indicate that the LR, BLR, and score test methods tend to be liberal. Fieller’s method is still generally conservative

Fig. 2 A robustness comparison for the four methods of interval estimation of the ED₅₀, when the true dose–response is the probit model. Two dotted lines denote the left and right endpoints of the range $\omega = (-0.5, 0.5)$, respectively. The fractions in the key denote the proportion of points in ω

for small sample sizes, but as n_i becomes larger, it becomes more liberal. The performances of all four methods are similar. They are robust in more than 50% of the cases considered.

The Cubic Logistic Model

For the simulation results shown in Fig. 3 based on data sets (a) and (b), it can be seen, by noting the proportion of points inside ω , that the BLR and score test methods are more robust than the Fieller and LR methods, which have only 5 robust results out of the 60 considered for the LR method. In addition, the Fieller and score test methods are almost always conservative, while the LR and BLR methods are sometimes conservative and sometimes liberal.

The simulation results shown in Fig. 3 based on data set (c), indicate that 82, 96, 107, and 103 out of 120 results are within ω for the Fieller, LR, BLR, and score test methods, respectively. Thus all four methods of interval estimation are, to some degree, robust.

Fig. 3 A robustness comparison for the four methods of interval estimation of the ED₅₀, when the true dose–response is the cubic logistic model. Two dotted lines denote the left and right endpoints of the range $\omega = (-0.5, 0.5)$, respectively. The fractions in the key denote the proportion of points in ω

The Asymmetric Aranda–Ordaz Model

For the simulation results shown in Fig. 4 based on data sets (a) and (b), Fieller’s method tends to be conservative. The BLR and score test methods can also be conservative. The LR method can be quite liberal at times, when the other three methods are not. Overall, none of the four methods can really be classified as being robust.

For the simulation results shown in Fig. 4 based on data set (c), all four methods of interval estimation appear to show a good degree of robustness overall. It follows from the proportion of points inside ω that the performance of all four methods is reasonably comparable.

Summary

When the true dose–response curve is the probit model, none of the methods of interval estimation are robust for the configurations given by data sets (a) and (b). All four methods display a similar performance for the data set (c)

Fig. 4 A robustness comparison for the four methods of interval estimation of the ED₅₀, when the true dose-response is the asymmetric Aranda-Ordaz model. Two dotted lines denote the left and right endpoints of the range $\omega = (-0.5, 0.5)$, respectively. The fractions in the key denote the proportion of points in ω

configurations, and they are robust in more than one-half of the configurations considered.

For a true cubic logistic dose-response relationship, the BLR and score test methods perform best. They are at their most robust for the data set (c) configurations, where the other two methods also perform satisfactorily.

For departures from a logistic model given by the asymmetric Aranda-Ordaz model, the absolute performance of all four methods is very poor, specifically for the Fieller and LR methods, for data sets (a) and (b); on the other hand, the absolute performance of all four methods is very good for data set (c).

Robustness of Interval Estimators of the ED₉₀

The Probit Model

For the simulation results shown in Fig. 5, the performance of the LR, BLR, and score test methods is similar and

Fig. 5 A robustness comparison for the four methods of interval estimation of the ED₉₀, when the true dose-response is the probit model. Two dotted lines denote the left and right endpoints of the range $\omega = (-0.5, 0.5)$, respectively. The fractions in the key denote the proportion of points in ω

somewhat better than that of the Fieller method. However, none of the methods is robust in more than three quarters of the cases considered.

The Cubic Logistic Model

The results displayed in Fig. 6 show that in all three sets of experimental configurations, the performance of Fieller's method is poorer than those of the other three methods, which are similar in their performance, and are robust in at least two-thirds of the cases considered.

The Asymmetric Aranda-Ordaz Model

The simulation results shown in Fig. 7 suggest that the absolute performance of the Fieller method is always slightly inferior to those of the LR, BLR, and score test methods, which display a similar performance and achieve a result in ω in at least 50% of occasions.

Fig. 6 A robustness comparison for the four methods of interval estimation of the ED₉₀, when the true dose–response is the cubic logistic model. Two dotted lines denote the left and right endpoints of the range $\omega = (-0.5, 0.5)$, respectively. The fractions in the key denote the proportion of points in ω

Summary

When the true dose–response models are either probit, cubic logistic, or asymmetric Aranda–Ordaz, the overall performances of the LR, BLR, and score test methods are similar, and noticeably better than that of Fieller’s method. The LR, BLR, and score test methods achieved a reasonable level of robustness.

CONCLUSION

Overall, using the definition of robustness given in “Simulation Results,” the BLR and score test methods are the most robust of the four methods of interval estimation of the ED₅₀ for the range of true models considered here. However, even their performance is poor in a number of the configurations studied. This is usually true when the sample size is much smaller, such as in data sets (a) and (b).

The results obtained under departures from the logistic model given by the two extended models are encouraging. Overall, all four methods of interval estimation of the ED₅₀

Fig. 7 A robustness comparison for the four methods of interval estimation of the ED₉₀, when the true dose–response is the asymmetric Aranda–Ordaz model. Two dotted lines denote the left and right endpoints of the range $\omega = (-0.5, 0.5)$, respectively. The fractions in the key denote the proportion of points in ω

are robust to some degree. However, as might be expected, there are differences according to the degree of departure from the logistic model. When the true dose–response relationship is cubic logistic, combining the results for all four methods for data set (c), when $\gamma = 1$, 88% of the results are robust; this figure drops to 65% for $\gamma = 10$. This is possibly not surprising, as $\gamma = 10$ appears to be a sizable departure in absolute terms. The asymmetric Aranda–Ordaz model provides a more interesting scenario. Departures from the logistic model, given by values of λ greater than 1, appear to give rise to fewer robust results than departures by an equivalent amount given by values of λ less than 1. For example, when $\lambda = 1.2$, 64% of results are robust, compared with 81% when $\lambda = 0.8$. Thus departures above $\lambda = 1$ may not have to be that great to render the methods nonrobust.

On the whole, for the ED₉₀, Fieller’s method did not perform usually as well as the LR, BLR, and score test methods, which achieve a reasonable level of robustness.

From the results presented here, one might say that the BLR and score test methods could be viewed as safer methods to use for interval estimation of effective doses in the presence of model misspecification.

Enrichment Design

Jen-pei Liu

Division of Biometry, Department of Agronomy, and Institute of Epidemiology, National Taiwan University, Taipei, Taiwan; and Division of Biostatistics and Bioinformatics, Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Taiwan

Abstract

The main objective of an enrichment design is to screen for possible responders using the active treatments under investigation. This entry serves as a brief review of the phases of an enrichment design and the process by which they are conducted.

Keywords: Enrichment; Holter monitoring; Targeted clinical trials; Screening.

INTRODUCTION

In clinical trials, the target population is defined by the inclusion and exclusion criteria. As a result, a screening period is usually conducted for the purpose of identifying the eligible subjects before actually enrolling them into the study. On the other hand, a placebo run-in period is also usually performed after the screening period and before the double-blind, randomized, active treatment period to assess the patient's compliance and to estimate the potential placebo effect. Both the screening and placebo run-in periods can be viewed as sequential screening processes for the identification of the patients who meet the inclusion/exclusion and compliance criteria without giving the active treatment under investigation to the patients.

The objective of some trials is to evaluate the pharmaceuticals or treatments based on hard efficacy endpoints such as death, myocardial infarction, or bone fracture. However, these hard endpoints require a long follow-up period to observe. On the other hand, some short-term responses can be obtained much more quickly for some soft endpoints such as biological markers. In addition, some therapeutic agents are likely to be effective in a population of the patients who may have an underlying disorder that is responsive to the manipulation of dose levels of the agents or several agents. Therefore it is necessary to perform some additional screening processes using the active treatments under evaluation after either the screening period or the placebo run-in period to identify the candidates in whom test agents are likely beneficial in the early phase of the trial. This phase of an additional screening process of the same therapeutic agent or test of different agents for the identification of patients with drug efficacy is called the enrichment phase. The patients with drug efficacy identified in the enrichment phase are then randomized to receive either the efficacious dose (agent) or the matched

placebo or the active controls. This type of the design with additional screening processes with the active treatments evaluated in the study is called the enrichment design.^[1] According to this definition, the difference between the designs, with either screening or placebo run-in periods, and the enrichment designs is that the active treatments are used to identify the patients.

EXAMPLES

An enrichment design usually consists of at least two phases. The first phase is the enrichment phase, in which a titration design is usually conducted to classify patients into groups according to whether the pharmaceuticals under investigation present some benefits to the patients. The second usually is a randomized double-blind phase, possibly with a placebo concurrent control to investigate the effectiveness and the safety of the test agents in these patients formally and rigorously. The primary efficacy endpoints used for the evaluation during the two phases of an enrichment design, depending upon the objectives of the trial, can be the same or different. The concept of enrichment design is illustrated in three clinical trials in the areas of Alzheimer's disease and arrhythmia that have been described in detail in Chow and Liu.^[2]

The enrichment design was elected for a clinical trial conducted in the early development stage of tacrine, with doses of 40 and 80 mg four times a day in the treatment of patients with probable Alzheimer's disease. As indicated in Davis et al.,^[3] because of the clinical, biochemical, and pathological heterogeneity of the disease and clinical experience, not all patients with probable Alzheimer's disease would respond to any single treatment, and those who did respond might do so only within a limited dose range. Consequently, an enrichment design was elected to encounter

the above situations. This trial consisted of a total of four phases: a six-week double-blind dose-titration enrichment phase, a two-week placebo baseline phase, a six-week randomized, double-blind, placebo-controlled phase, and a six-week sustained active phase. After the patients met the inclusion and exclusion criteria, they were enrolled into the enrichment phase of the trial that consisted of three titration sequences. Each titration sequence consists of three two-week dosing periods. The dose in each titration sequence is always titrated up from 40–80 mg four times a day with a placebo in dosing periods 1, 2, and 3 for titration sequences 1, 2, and 3, respectively. The patients were randomized into one of the three titration sequences that were conducted in a double-blind fashion. The potentially therapeutic responses for each patient at each dose were then assessed at the end of each two-week dosing period. The “best dose” response for a patient was defined in advance in protocol as a reduction of at least four points from the screening value in a total score on the Alzheimer’s Disease Assessment Scale (ADAS)^[4] and without intolerable side effects. Patients with the identified “best dose” were then entered into a two-week placebo baseline period with the hope that this period would be sufficiently long for tacrine to wash out from the body and for patients to return to the screening pretreatment status with comparable efficacy outcomes. At the end of the two-week placebo baseline phase, the patients with a reduction of at least four points in ADAS during the enrichment phase entered the subsequent 6-week randomized, double-blind, parallel-group, placebo-controlled phase. They were randomized either to the active tacrine at their best dose or to the matched placebo. Patients who completed the six-week double-blind phase then entered into the sustained active treatment phase. As a result, the purpose of the selection of an enrichment design with three titration sequences for this study is to identify a group of patients who are likely to respond to tacrine at a certain dose; after a wash-out period of two weeks, these identified patients were randomized to either tacrine at their best dose or to placebo concurrent control in a double-blind phase.

The rationale for the selection of the enrichment design in one of the trials during the development of tacrine is to verify whether a short-term response to tacrine has predictability for the long-term efficacy in the prevention of progression of the patients with probable Alzheimer’s disease. The same primary efficacy endpoints such as ADAS or the Clinical Global Impression of Change were used in both the enrichment and double-blind phases for the evaluation of tacrine’s effectiveness. On the other hand, for other therapeutic agents, the real efficacy endpoint is mortality, which requires a long time to observe. Therefore the short-term efficacy of the agents is assessed by some other objective surrogate endpoints. It is then very important to know whether the short-term efficacy based on surrogate endpoint is predictive of the hard endpoint such as mortality. As a result, the enrichment design is

usually employed for the identification of the “short-term” responders at the initial stage followed by the main phase of the long-term study. Examples of this type of the trials can be found in the area of arrhythmia such as the Cardiac Arrhythmia Suppression Trial (CAST)^[5–7] and the Electrophysiologic Study versus Electrocardiographic Monitoring (ESVEM).^[8–12]

Cardiac Arrhythmia Suppression Trial is a multicenter, randomized, placebo-controlled study used to test the hypothesis whether the suppression of asymptomatic or mildly symptomatic ventricular arrhythmia after myocardial infarction would reduce the rate of death from arrhythmia. The drugs include two class-IC antiarrhythmic agents, encainide and flecainide, and moricizine with a placebo concurrent control. One of the objectives of the study is to test the predictability of adequate suppression of ventricular arrhythmia by the active drugs based on the ventricular premature contractions (VPC) as recorded by Holter monitor for mortality. As a result, an open-label enrichment design with two titration sequences involved with only active drugs was selected for this study. Patients with ejection fraction of at least 30% were randomly assigned to the two titration sequences: (encainide, moricizine, flecainide) or (flecainide, moricizine, encainide). The reason for the insertion of moricizine in the middle dosing period is its inferior efficacy in the suppression of VPC as compared with the other two active agents. Each drug is tested at two dose levels. The doses were 35 and 50 mg three times a day (tid) for encainide; 100 and 150 mg twice a day for flecainide; and 200 and 250 mg tid for moricizine. Because flecainide exhibits negative inotropic properties, it was not administered to the patients with an ejection fraction of less than 30%. The titration sequences for the patients with an ejection fraction of less than 30% were (encainide, moricizine) or (moricizine, encainide). The pre-specified criteria for an adequate suppression of ventricular arrhythmia were (i) a reduction of at least 80% in VPC and (ii) a reduction of at least 90% runs of unsustained ventricular tachycardia as measured by the 24-hour Holter recording four to ten days after each dose was begun. The titration process for a particular patient was stopped as soon as a drug and a dose were found to yield an adequate suppression. The patients whose arrhythmia was adequately suppressed were then randomized to either the “best drug” identified during the enrichment phase or to placebo for a three-year long-term follow-up.

The results of CAST indicate that the short-term efficacy measured as suppression of VPC based on Holter noninvasive ambulatory electrocardiographic monitoring might not be a good predictor for the long-term hard mortality endpoint. Others suggested that the failure to induce ventricular tachycardia or fibrillation by some drug assessed by the invasive electrophysiologic study might be a good independent predictor of the recurrence of arrhythmia. Consequently, the ESVEM trial was the first large

prospective, randomized trial conducted to compare the two methods in the predictability of long-term recurrence of arrhythmia by the short-term efficacy assessed by the two methods.^[8,10,11] Because it requires correlating the difference in recurrence rates of arrhythmia with the short-term efficacy by both methods, an inpatient enrichment phase was elected to identify a group of patients in whom a test drug exhibited a short-term efficacy assessed by either one of the two methods. After the patients had fulfilled entry criteria and 48-hour Holter monitoring and electrophysiologic study criteria, they were randomized to one of the two parallel groups for the two methods to assess the short-term drug efficacy. The first group employed non-invasive ambulatory electrocardiographic monitoring; the second group applied the invasive electrophysiologic study. Within each group, the patients received up to six arrhythmia agents in a random order until one drug was predicted to be efficacious or until all drugs have been tried that the patients were eligible to receive. A test drug was identified as effective as assessed by electrocardiographic monitoring during the inpatient enrichment phase if the following predefined criteria for short-term efficacy were met: (i) 70% reduction in mean VPC; (ii) 80% reduction in pairs of VPC; (iii) 90% reduction in mean ventricular tachycardia count; and (iv) absence of any runs of ventricular tachycardia longer than 15 seconds. Drug effectiveness evaluated by the electrophysiologic study during the enrichment phase is defined as the failure by the drug to induce a run of ventricular tachycardia longer than 15 seconds with V1V2V3 stimulation at the right ventricular apex. If a drug was proven to be efficacious for a patient during the enrichment phase, then that patient was discharged from the hospital for the long-term follow-up with the drug, and the accuracy of the prediction of efficacy is determined during the long-term follow-up. Patients in whom no drugs were proven to be effective during the enrichment phase were not randomized and were withdrawn from the study, but their vital signs and recurrence of arrhythmia were monitored. Enrichment design can also be used for the studies in non-responders or in the patients intolerant of another agent. Temple^[1] provided examples in the studies for severe hypertension and psychotropic agents.

The disease targets at the molecular level can be identified after completion of the Human Genome Project (HCP). Hence, treatment modalities specific for the patients with the identified molecular targets have been evaluated in the targeted clinical trials. Because only the patients tested positive for the molecular targets are enrolled and randomized into the targeted clinical trials, enrichment design is one of the most commonly employed design for the targeted clinical trials, examples are ALTTO trials,^[13] TAILORX trials,^[14] and MINDACT trial.^[15] Simon and Maitournam^[16] and Maitournam and Simon^[17] have discussed requirement of the sample sizes between the targeted clinical trials versus untargeted trials. In addition,

Liu and Lin^[18] and Liu et al.^[19] have suggested the use of EM algorithm for statistical inference of treatment effects for targeted clinical trials under enrichment.

CONCLUSION

The main objective of an enrichment design is to screen for possible responders using the active treatments under investigation. However, if a placebo is also included in the enrichment phase, then the possible placebo responders will also be identified in the enrichment phase. In addition, as demonstrated in the previous discussion, the design employed in the enrichment phase is usually a dose titration design with no wash-out periods between dosing interval. As a result, the treatment effects, carryover effects, and time effects all confound one another during the process of identification of responders. In CAST or ESVEM, the patients were randomized as soon as the first drug at the first dose was found to yield an adequate suppression of VPC. Another issue for the enrichment design therefore is whether or not the response observed is the best drug at its optimal dose for the responder. On the other hand, because of either a lack of randomization or different methods of randomization for the enrichment phase, statistical methods for analysis based on the data from both enrichment phases and double-blind phase of the trial are not fully developed. In summary, enrichment design further restricts the target population into a very small selective group. However, sometimes, it is not yet possible to distinguish this small group of patients from the rest with the same ailment in terms of demographic and other prognostic factors for grassroots clinical practice. Therefore, inference based on the statistical analysis for a trial using an enrichment design remains a challenge for all of us.

Abstract

Clinical trials can be enriched on subpopulations that may be more responsive to treatments to improve the chance of trial success. In 2012, Food and Drug Administration issued a draft guidance to facilitate enrichment design, where it pointed out the uncertainty on the subpopulation classification and on the treatment effect outside of the identified subpopulation. Related statistical literature is reviewed, and the developed enrichment design with patient population augmentation is described in this entry. In this newly developed design strategy, the identified subpopulation (biomarker positive) is augmented by some biomarker-negative patients, so that there is sufficient power to assess both the treatment effect in the biomarker-positive subpopulation and the overall treatment benefit. A weighted statistic is used to assess the overall treatment effect for this assessment, correcting for the disproportionality of biomarker-positive and biomarker-negative subpopulations under enriched trial setting. Screening information is utilized for weight determination.

Keywords: Biomarker; Enrichment design; Overall treatment effect; Screening; Two-step design; Weighted estimator.

INTRODUCTION

Enrichment designs have been widely discussed to establish treatment benefit in a selected (enriched) subpopulation. In this entry, literature and common practice of enrichment design is reviewed, and a newly proposed enrichment design with patient population augmentation is described.

BACKGROUND

In the past decades, enrichment designs have emerged and gained popularity in clinical development and subsequently in statistical research for trial design.^[1–7] They are closely related to the Food and Drug Administration (FDA)’s initiative on personalized medicine.^[8] One purpose to select such enriched population is to increase trial sensitivity of treatment response, e.g., the *Trastuzumab* benefit on HER2+ breast cancer patients.^[9–12] This type of enrichment is typically referred to as *predictive enrichment* and will be the focus of this entry. Specifically, predictive enrichment selects patients who are more likely to respond to a treatment of interest than other patients, so as to generate a larger treatment effect size and to permit use of a smaller study size. Typically, the predictive enrichment

selection maneuvers are well rationalized without controversy, and trial results are interpreted accordingly for the selected subpopulation. This is in contrary to the conventional “all-comer design” which refers to a clinical trial that enrolls general disease population, often referred as all-comer population, and makes inference on the (overall) treatment effect for the general disease population.

Several considerations arise and subsequently statistical methodology are proposed during the evolved thinking of predictive enrichment clinical trials, and the considerations can be divided into trial design perspective and data analysis perspective.

Design Aspect

When a predictive biomarker is adequately identified, a typical enrichment design enrolls only biomarker-positive patients. It is considered to be more efficient than an all-comer design as illustrated by Simon and Maitourman.^[2,3] The terminology “biomarker-positive” and “biomarker-negative” are used to denote the enriched subpopulation and its complementary (i.e., patients not satisfying the enrichment criteria), respectively. When such a biomarker is a post-treatment pharmacodynamics marker, a run-in design^[13,14] can be used to classify all-comers into biomarker-positive or biomarker-negative patients in the

first stage of the trial and patients are randomized in the second stage of the trial. In typical biomarker-based designs with or without a run-in stage, depending on the strength of prior evidence either only biomarker-positive patients are randomized or all patients are randomized stratified by the biomarker status (i.e., stratified all-comer design). A comprehensive review of biomarker-based design and testing strategies is provided by Freidlin and Korn.^[15]

In 2012, FDA issued a draft guidance on enrichment design.^[16] The guidance suggested inclusion of biomarker-negative patients to assess “the *uncertainty* about the marker cutoff and responsiveness of marker-negative patients.” Such uncertainty is not unreasonable considering multiple disease pathways, less-than-perfect accuracy of biomarker assays, and the uncertainty around the cutoff values to define biomarker-positive versus biomarker-negative patients, etc. One example is again the development of HER2-targeting agents and the *Trastuzumab* treatment for adjuvant breast cancer. In a retrospective analysis of a pivotal *Trastuzumab* adjuvant trial, 174 cases found actually lacked HER2 gene amplification, and they still benefited as much as HER2-positive patients.^[17] These findings were confirmed in a similar analysis from an independent *Trastuzumab* adjuvant study.^[18] Biological evidence suggested that efficacy of HER2-targeting agents may be through breast cancer stem cell, and the regulation of breast cancer stem cell by HER2 may extend beyond HER2 gene amplification.^[19]

In the presence of such uncertainty, although typical enrichment design (which only studies biomarker-positive patients) can achieve better trial efficiency in terms of a smaller sample size, it comes at the expense of lacking the ability to make inferences for an all-comer population. As the FDA guidance has explicitly requested to include biomarker-negative patients in enrichment design, or more importantly when there could be potential treatment effect in the biomarker-negative subpopulation and therefore the overall treatment effect in an all-comer population is also of interest, an enrichment design that randomizes biomarker-positive patients only may not be sufficient. On the other hand, if an all-comer population is randomized using the stratified all-comer design, the efficiency associated with the enrichment trial design feature is then lost. It would become a challenge, particularly when the biomarker-positive subpopulation is relatively small, that a large number of biomarker-negative patients have to be enrolled into such a trial in order to be able to recruit sufficient number of biomarker-positive patients. As an illustrative example, consider a 2-arm design where 468 patients are needed to provide 90% power to detect a treatment difference of 1.5 with σ of 5.0 at two-sided α of 0.05. Under a typical enrichment design to study biomarker-positive patients only, the study size would be 468. Under a stratified all-comer design, the study size would be 2,340 where biomarker-positive patients only account for 20% of the general disease population, which becomes a very large trial to enroll.

As an alternative, adaptive enrichment has been proposed in literature where biomarker-negative patients are also assessed as part of the trial design. Wang, Hung, and O'Neill^[20] proposed to start with an all-comer trial and use interim data to decide whether to continue with the all-comer trial or to enrich on one of the prespecified candidate biomarker-positive subpopulations. This design has the advantage of flexibility but suffers from the analysis and operational complexity of all adaptive trials. More importantly, depending on the strength of the interim data for enrichment decision-making, such designs could have the risk of making incorrect interim decision, resulting in wasting or losing a subpopulation. This is particularly a concern when randomization is not stratified for all candidate biomarker-positive subpopulations so bias can exist in the evaluation, or in situations where the candidate biomarker-positive subpopulations are small and therefore their interim data are limited and lack of power. A different type of adaptive enrichment was proposed by Simon and Simon,^[21] where the enrollment of each individual patient is determined via a probability calculation for potential treatment benefit after certain initial assessment period. Aside from the common adaptive design-associated features, Simon and Simon's approach lacks a systematic enrichment biomarker and therefore potentially lacks a clinically meaningful rationale or interpretation for such enrichment.

Analysis Aspect

In the enrichment design methods mentioned above, when the analysis (or final analysis in adaptive trials) is conducted on the biomarker-positive subpopulation only, standard analysis techniques can be directly applied. However, when a trial is enriched in a biomarker-positive group with some biomarker-negative patients included, statistical analysis needs to account for this design feature. There are two issues to be addressed—multiplicity adjustment for testing on multiple populations (biomarker-positive subpopulation and all-comer population) and inference of overall treatment effect for all-comer population. Commonly used approaches to handle multiplicity adjustment include sequential testing and splitting family-wise type I error rate.^[14,15] Several of the above mentioned design philosophies start the treatment assessment with all-comer population and proceed to biomarker-positive enrichment if all-comer population fails or is not likely to succeed. Therefore, assessment in the promising biomarker-positive subpopulation can be at risk because it is not the first step of statistical testing. Splitting type I error rate can mitigate the risk of mis-specifying the testing sequence as always, and the challenge shifts to how the type I error rate should be split, e.g., 0.01/0.04 or 0.04/0.01. In addition, it comes with the expense that the known-to-be-promising biomarker-positive subpopulation is not tested on the full type I error rate of 0.05, paying a multiplicity penalty for the less promising all-comer population. The multiplicity

penalty in the adaptive enrichment is similar but in a more complex manner.^[20,21]

How the overall treatment effect is estimated when the proportion of biomarker-positive patients in an enrichment design is typically larger (enriched) than that in an all-comer trial composition is another issue. Naive analysis via a simple pooling of biomarker-positive and biomarker-negative patients which did not take into account this disproportionality has been seen. One example is the TIMI (Thrombolysis in Myocardial Infarction) 38 study^[22] where two subpopulations were studied—it randomized 10,074 acute coronary syndromes (ACS) patients with non-ST elevation myocardial infarction (NSTEMI) which was the enriched subpopulation and 3534 ACS patients with STEMI. When treatment effect was established in the enriched NSTEMI subpopulation, a simple pooling of the two subpopulations was conducted by the sponsor to evaluate the overall treatment effect as if the trial was conducted in an all-comer trial composition. This analysis was improper because the proportion of the NSTEMI patients was inflated in the analysis. Therefore, new statistical techniques are needed in order to appropriately estimate the overall treatment effect under the enrichment trial setting.

In a newly proposed enrichment design with patient population augmentation,^[23] the biomarker-positive subpopulation is the primary focus, but this subpopulation is augmented with appropriate number of biomarker-negative patients. A weighted estimator is used to obtain proper statistical inference for the overall treatment effect in an all-comer population. If prior evidence suggests treatment benefit in biomarker-positive patients, a study such that the chance of trial success in biomarker-positive subpopulation is maximized, followed by the establishment of treatment benefit in an all-comer population with the addition of biomarker-negative patients could be designed. In contrast to randomizing all available subjects, the latter goal is achieved while maintaining the “enriched” design feature for trial efficiency. Comparison of this methodology with other enrichment design methods in literature is summarized in Table 1.

METHODS

Overall Treatment Effect in an All-Comer Population

Consider a typical randomized controlled two-arm clinical trial setting, where an experimental drug is compared to a control and the treatment effect is measured by treatment difference in response values. The trial enrolls both biomarker-positive patients and biomarker-negative patients.

Let Y_{+e} and Y_{-e} denote the response of a random biomarker-positive patient and a random biomarker-negative patient, respectively, in the experimental arm, both of which are normally distributed. Let W denote the biomarker-positive indicator, where $W \sim \text{Bernoulli}(p)$. Let Y_e denote the response of a patient randomly selected from the experimental arm. Then:

$$Y_e = WY_{+e} + (1 - W)Y_{-e} \quad (1)$$

Similarly for the control arm,

$$Y_c = WY_{+c} + (1 - W)Y_{-c} \quad (2)$$

Therefore,

$$Y_e - Y_c = W(Y_{+e} - Y_{+c}) + (1 - W)(Y_{-e} - Y_{-c}) \quad (3)$$

The expected treatment difference in a general patient population, i.e., in an all-comer population, is as follows:

$$\delta = E[Y_e - Y_c] = E[E[Y_e - Y_c | W]] = p\delta_+ + (1 - p)\delta_- \quad (4)$$

where δ_+ and δ_- are the expected treatment difference in the biomarker-positive subpopulation and the biomarker-negative subpopulation, respectively. When the overall treatment effect in an all-comer population is of interest, δ becomes the parameter of interest.

Table 1 Comparisons of different enrichment design methods

	Trial population	Treatment effect inference	Screening data used
Traditional enrichment design	Biomarker-positive only	Biomarker-positive only	No
Stratified all-comer design including “run-in” design	All comer	1. Biomarker positive then biomarker negative 2. Biomarker positive then all comer 3. All comer then biomarker positive 4. α splitting for biomarker positive and all comer	No
Adaptive enrichment	All comer then potentially biomarker positive	All comer then potentially biomarker positive	No
Enrichment with patient population augmentation	Biomarker positive and biomarker negative, enriched on biomarker positive	1. Biomarker positive then all comer 2. α splitting for biomarker positive and all comer	Yes

Weighted Estimator of Overall Treatment Effect

Under stratified randomization by the biomarker status, δ in Eq. 4 can be estimated by:

$$\hat{\delta} = \hat{p}\hat{\delta}_+ + (1 - \hat{p})\hat{\delta}_- \quad (5)$$

where $\hat{\delta}_+$ and $\hat{\delta}_-$ are the estimated treatment difference in the biomarker-positive and biomarker-negative subpopulations, respectively, and $\hat{p}$ is obtained at the screening stage to estimate the proportion of biomarker-positive patients under the real-world disease prevalence. Therefore, when a trial is enriched for the biomarker-positive subpopulations, $\hat{p}$ will adjust the contribution of biomarker-positive data and biomarker-negative data in estimating the overall treatment effect, so their contributions are aligned as in an all-comer population. It can be shown that $\hat{p}$ is an unbiased and consistent estimate of δ .

The variance of the proposed weighted estimator, again under stratified randomization, can be explicitly derived as:

$$\begin{aligned} \text{Var}[\hat{\delta}] = & \left(p^2 + \frac{p(1-p)}{m} \right) \frac{2\sigma_+^2}{n_+} \\ & + \left((1-p)^2 + \frac{p(1-p)}{m} \right) \frac{2\sigma_-^2}{n_-} \\ & + \frac{p(1-p)}{m} (\delta_+ - \delta_-)^2 \end{aligned} \quad (6)$$

where m is the number of screened patients, n_+ and n_- are the number of randomized patients per treatment arm in the biomarker-positive subpopulation and biomarker-negative subpopulation, respectively, and σ_+^2 and σ_-^2 are the common variance of response (common for the experimental arm and control arm) in the biomarker-positive subpopulation and the biomarker-negative subpopulation, respectively. $\hat{p}$, $\hat{\delta}_+$, $\hat{\delta}_-$ and sample variance for σ_+^2 and σ_-^2 can be plugged into $\text{Var}(\hat{\delta})$ to get a consistent variance estimator. Statistical inference follows by constructing a Z-test based on asymptotic normal distribution of $\hat{\delta}$.

Trial Design and Sample Size Considerations

In line with the enrichment philosophy, a two-step sample size determination strategy can be utilized. Specifically, the biomarker-positive subpopulation is sized first with power $(1 - \beta)$ (step I) at two-sided α to test for δ_+ . Knowing the sample size of the biomarker-positive subpopulation, the sample size of the biomarker-negative population is then calculated to achieve power $(1 - \beta')$ (step II) at two-sided α' when testing for δ . This calculation is carried out by solving:

$$\text{Var}(\hat{\delta}) = \frac{\delta^2}{(Z_{\alpha'/2} + Z_{\beta'})^2} \quad (7)$$

Table 2 Illustrative sample size and power calculations

p	Biomarker+	Overall n, (n ₊ /n)		
	n ₊	$\beta' = 90\%$	$\beta' = 80\%$	$\beta' = 70\%$
0.2	234	535 (0.44)	454 (0.52)	405 (0.58)
0.3	234	464 (0.50)	399 (0.59)	360 (0.65)
0.4	234	410 (0.57)	355 (0.66)	325 (0.72)

Note: Parameter settings: $\delta_+ = 1.5$; $\delta_- = 1.0$; $\sigma_+ = \sigma_- = 5$; $m = 2 \times n_+/p$; $\alpha = \alpha' = 0.05$, two-sided; $\beta = 90\%$; and $\beta' = 70\%$, 80% , and 90% .

with δ in Eq. 4 and $\text{Var}(\hat{\delta})$ in Eq. 6 and with given n_+ and $m = 2 \times n_+/p$. Note that it requires the value of p , and usually a good estimated value can be obtained from external sources prior to trial start.

When sequential testing is planned, α and α' would be the same, typically at 0.05. Under the enrichment philosophy, it is reasonable to test first for δ_+ on the biomarker-positive subpopulation and then for δ on the overall trial population. When type I error rate splitting is planned, α and α' can take different values. Again under the enrichment philosophy, the biomarker-positive subpopulation is recommended to be fully powered at 90% power, and therefore β is 10%. β' can be set as same as β if time and resource of drug development allows. It can also be set higher than β from a practical perspective. For example, β is 10% and β' is 30%, so we size the enriched subpopulation for 90% power and the total trial population for 70% power.

Table 2 presents illustrative calculations for power and sample size under this enrichment design. It can be seen that the real trial composition of biomarker-positive subpopulation, n_+/n , is larger than p which is the prevalence of biomarker-positive patients in general disease populations. It confirms that the weighted estimator down-weighs biomarker-positive data to its prevalence rate, so the overall treatment effect is not driven by the enriched biomarker-positive subpopulation. In addition, it can be seen that larger the p , the smaller the n , meaning that fewer biomarker-negative patients are to be enrolled because the biomarker-positive sample size n_+ remains at 234 to maintain 90% power in this subpopulation.

CONCLUSIONS AND DISCUSSIONS

Enrichment design has been around for a long time but is not widely used. One leading cause is that once we restrict the study population to biomarker-positive patients only, we are only able to establish treatment effect in this subpopulation and thus miss the opportunity to investigate the overall treatment effect in a broad patient population. In the newly proposed enrichment design method, biomarker-positive subpopulation is augmented by additional biomarker-negative patients and so the overall treatment effect can also be assessed. This design has the advantages of retaining a

design and analysis priority for the promising biomarker-positive subpopulation. At the same time, it allows the assessment of the overall treatment effect while maintaining the “enriched” feature of trial design for efficiency, compared to enrolling a large all-comer population. Not all these features can be achieved simultaneously via previous enrichment design approaches.

In order to make correct inference on the overall treatment effect when the biomarker-positive subpopulation is over-represented under the “enriched” trial setting, a weighted estimator is used to combine the treatment effect in the biomarker-positive and biomarker-negative subpopulations at appropriate level. The weighted estimator down-weights the enriched biomarker-positive data and thus will not let the treatment effect in biomarker-positive subpopulation to drive the overall treatment effect. An explicit variance formula for this weighted estimator is derived, which allows for explicitly powering the overall treatment effect, and thus facilitates simple sample size formulation.

Another important feature of the design is the use of screening data. Unlike usual clinical trials that screening data is ancillary for data analysis and definitely not contributing to trial design and sample size planning, screening data are involved in both trial design and data analysis under this new approach. This is *to our knowledge the first time* that screening information is incorporated into clinical trial design and analysis.

To summarize, clinical trials are expensive and time-consuming to conduct, and therefore a carefully selected design strategy can greatly help reduce the cost and expedite drug development. The new enrichment design with patient population augmentation is advocated when there is evidence of a promising treatment effect in a biomarker-positive subpopulation and there is uncertainty on the treatment effect in the complementary biomarker-negative subpopulation, especially when prevalence rate of the biomarker-positive subgroup is not high (e.g., ≤ 0.5).

Abstract

Equivalence trials attempt to compare a test treatment to an active control or the standard therapy. By giving statistical examples, this entry discusses benefits and methods of conducting equivalence trials.

Keywords: Average bioequivalence; Confidence intervals; Individual bioequivalence; Population bioequivalence.

INTRODUCTION

Most of the trials conducted during the developmental stage of investigational pharmaceuticals before filing the New Drug Application (NDA) or Product License Application (PLA) are for demonstration of better efficacy and safety of the test product over the concurrent placebo control. This type of trial is referred to as the superiority trial. On the other hand, some trials try to compare the test treatment to an active control such as some reference treatment or the standard therapy. The purpose of this type of trial is to verify whether the effectiveness or safety of the test treatment is similar to that of the active control. Depending on its objectives, this type of trial can be further classified into equivalence or non-inferiority trials.

After the patent of an innovative product expires, other pharmaceutical companies can manufacture generic copies under the Drug Price Competition and Patent Term Restoration Action passed in 1984 through the Abbreviated New Drug Application (ANDA) based on the pharmacokinetic (PK) responses derived from plasma or blood concentrations collected from bioequivalence studies, such as area under the plasma concentration–time curve (AUC) or the peak concentration (C_{max}). In order to reduce the variation, crossover designs with normal volunteers are usually employed for bioequivalence testing.^[1] Based on the “Fundamental Bioequivalence Assumption,”^[2] if the PK parameters of the generic and innovative products are close, within a pre-specified allowable limits, it is then assumed that they produce no clinically meaningful difference in effectiveness and safety and hence the generic drugs and the marketed innovative reference product can be used interchangeably. On the other hand, some drug products do not work through systemic absorption and have negligible plasma levels. These drugs include metered-dose inhalers (MDIs) indicated for the relief of

bronchospasm in patients with reversible obstructive airway disease, sucralfate for the treatment of acute duodenal ulcer and topical and vaginal antifungals. Because these drug products have negligible plasma concentration of the active ingredients, PK responses are no longer adequate for evaluation of bioequivalence between drug products. As a result, the U.S. Food and Drug Administration (FDA) suggested that clinical trials be conducted to demonstrate the therapeutic equivalence based on well-defined clinical endpoints.^[3,4] Both clinical equivalence or bioequivalence trials are required to demonstrate similarity based on either clinical endpoints or PK responses. They are referred to as “equivalence trials.”

For many diseases, there exists a standard drug that has been proved to be efficacious with a reasonably tolerable safety profile by more than one adequate well-controlled studies. But it is still worthwhile to develop new drugs for the same disease with similar efficacy if they can provide a better safety margin, are easy to administer, are less expensive, require a short duration of treatment, and can substitute for an invasive procedure. As a result, instead of a superior trial, it is sufficient for clinical trials to provide evidence that the new drug is therapeutically no worse than the standard reference treatments with respect to a pre-specified limit of no clinical significance.^[5–9] This type of trial is called the non-inferiority trial, which will be discussed in more detail in the entry *Therapeutic Equivalence*.

EQUIVALENCE TRIALS

The concept of equivalence asks for similarity in distributions of efficacy clinical endpoints or PK responses between the test and the reference drug. It is then referred to as “population equivalence.” Under the normality

assumption, the distributions of most PK responses or efficacy clinical endpoints or their transformation can be uniquely determined by the first two moments, the average and variability. Hence the equivalence between of the test and reference drug products can be established through the similarity of both the average and the variance. Average equivalence requires the similarity in averages of the distributions between the two drug products. On the other hand, population equivalence, under the normality assumption, asks for equivalence in both average and variability. However, in general, equivalence in the first two moments does not guarantee equivalence between distributions. But the assessment of equivalence between a test drug and a reference product, in general, focuses only on the comparison in averages. Only recently has some attention been paid to the equivalence in distributions of PK responses for generic products.^[10,11] For a complete description and recent development of bioequivalence, Chow and Liu^[2]. Chow and Liu^[9] provide further discussion on therapeutic equivalence. Failure to reject the null hypothesis of equality does not imply equivalence between the test and reference product.^[5,12–14] We hence use average as an example to demonstrate the concept of equivalence. Let μ_T and μ_R be the population averages of the test and reference products, respectively. The concept of the equivalence in average is that the difference in average is within the pre-specified allowable limits. In other words, the average of the test product is neither too low nor too high as compared with that of the reference product. As a result, the consumer's risk is the error for declaring average equivalence between the test and reference products when in fact they are not equivalent; the producer's risk is the error of declaring average inequivalence between the two products when in fact they are equivalent. The hypothesis of equivalence in terms of average can therefore be formulated as follows^[15]

$$\begin{aligned} H_0 : \mu_T - \mu_R \geq L \quad \text{or} \quad \mu_T - \mu_R \leq U \\ \text{vs.} \\ H_a : L < \mu_T - \mu_R < U \end{aligned} \quad (1)$$

where L and U are some pre-specified lower and upper equivalence limits, respectively.

Because the above alternative hypothesis is an interval, it is also called the “interval hypothesis of equivalence.” In addition, both lower and upper equivalence limits are required for interval hypothesis in Eq. (1). It is also referred to as “two-sided equivalence.” The interval hypothesis in Eq. (1) is the correct formulation of the hypothesis for the assessment of equivalence in such a manner that the type I error represents the consumer's risk and the type II error is the producer's risk. The selection of equivalence limits should require clinical or pharmacokinetic justification. For average bioequivalence, the FDA guidance^[16] requires a range of 80–125% for the ratio of average area under

curves or peak concentrations between the test product and the reference product.

The interval hypothesis in Eq. (1) can further be decomposed into two one-sided hypotheses as

$$\begin{aligned} H_{0L} : \mu_T - \mu_R \leq L \quad \text{vs.} \quad H_{aL} : \mu_T - \mu_R > L, \\ \text{and} \\ H_{0U} : \mu_T - \mu_R \geq U \quad \text{vs.} \quad H_{aU} : \mu_T - \mu_R < U \end{aligned} \quad (2)$$

A comparison of interval hypotheses in Eq. (1) and two one-sided test hypotheses in Eq. (2) reveals that the parameter space defined in the null hypothesis of the interval hypotheses is the union of the spaces defined in the two one-side null hypotheses. The parameter space defined by the alternative hypothesis in Eq. (2) is the intersection of the spaces of the two alternative hypotheses in Eq. (2). From the intersection–union principle (IUT,^[17]), for each of the two one-sided hypotheses, there is a level α test statistic to verify whether the average of the test product is not too low (high) as compared with that of the reference drug. Therefore if both null hypotheses of the two one-sided hypotheses are rejected at the pre-specified nominal significance level α , then equivalence in average between the test and reference products is also concluded at the α significance level. Because this procedure involves testing two one-sided hypotheses simultaneously, it is called the two one-sided tests procedure.^[2,18]

Because the equivalence between the two drugs is concluded only if the null hypothesis of both one-sided hypotheses is rejected at the pre-specified nominal level of significance, the two one-sided tests procedure can control the consumer's risk at the nominal level. However, if the variability is large or the sample size is too small, the two one-sided tests procedure may be very conservative in concluding equivalence. Hsu et al.^[19] and Brown et al.^[20] have proposed other procedures for the interval hypothesis of equivalence, which are claimed to be more powerful than the usual two one-sided tests procedure. However, their procedures are mathematically complicated and lack intuitive interpretation. The open non-convex shape of their rejection regions imply that any estimate of mean difference in average might conclude average equivalence as long as the standard error of the observed mean difference is sufficiently larger or if it increases to infinity. The hypothesis for evaluation of equivalence in variability can be similarly formulated^[2,21] as

$$\begin{aligned} H_0 : \sigma_T^2 / \sigma_R^2 \geq \delta_L \quad \text{or} \quad \sigma_T^2 / \sigma_R^2 \leq \delta_U \\ \text{vs.} \\ H_a : \delta_L < \sigma_T^2 / \sigma_R^2 < \delta_U \end{aligned} \quad (3)$$

where σ_T^2 and σ_R^2 are the variance of the test and reference product, respectively; $0 < \delta_L < 1 < \delta_U$ are the equivalence limits for evaluation of equivalence in variability. For

bioequivalence testing conducted under crossover design, they are referred to as the intrasubject variability. Under a standard two-sequence and two-period (2×2) crossover design, Liu and Chow^[21] proposed the Pitman–Morgan two one-sided tests procedure for Eq. hypothesis 3. Because each subject receives test or reference product only once under a 2×2 crossover design, estimators for σ_T^2 and σ_R^2 , and σ_T^2/σ_R^2 cannot be obtained without further assumptions. However, for PK responses obtained under replicated crossover designs, inference about equivalence based on σ_T^2/σ_R^2 including confidence interval is quite straightforward.^[2,21] This discussion about equivalence in average or variability can be applied to the responses obtained from either parallel designs or crossover designs. For bioequivalence trials using either the standard 2×2 or replicated crossover designs, see Chow and Liu^[2,15]. Chow and Liu^[2,22–24] have provided sample size determination for equivalence in averages.

CONFIDENCE INTERVAL APPROACHES

Although the discussion for assessment of equivalence is in the context of statistical hypothesis testing procedure, it also is an estimation problem. As a result, many have advocated the confidence interval approach to assessment of equivalence between the test and reference drug.^[2,6,13,14,25,26] The idea and procedure for the assessment of equivalence are quite straightforward. For two-sided average equivalence, if the nominal level is α , then the two drugs are concluded equivalent if the $100(1 - 2\alpha)\%$ confidence interval for the mean difference is completely contained within (L, U). The confidence interval approach is more appealing than the testing procedure because it can provide the magnitude and width of the average difference between the two drugs. In addition, the hypothesis testing and confidence interval approaches in some situations are in fact operationally equivalent.^[18] For many cases, the pivotal quantity for construction of confidence interval is the test statistic for the two one-sided tests procedure, which follows either a central t distribution or the standard normal distribution. As a result, for two-sided equivalence problem, the $100(1 - 2\alpha)\%$ confidence interval is totally contained within (L, U) if and only if both one-sided hypotheses in Eq. (2) are rejected at the α significance level.

EQUIVALENCE LIMITS

The decision for assessment of equivalence by either the confidence interval approach or the testing procedure depends upon the lower and upper equivalence limits and has nothing to do with whether the observed difference is zero or not. Table 1 illustrates the consistency between the two one-sided tests procedure and the confidence interval approach for the two-sided equivalence. As can be seen in Table 1, although the null hypothesis of equality is not rejected, the equivalence between the two drugs cannot be concluded because the 90% confidence interval may be too wide to be contained within the equivalence limits. Another situation is that the equivalence between the test and reference drugs is concluded because the confidence interval is very narrow and is totally contained within the limits although it does not contain 0. In other words, equivalence can be concluded even when the null hypothesis of equality is rejected; it is then concluded that there is a difference between the test and reference product. As a result, the length of equivalence interval, U–L for therapeutic equivalence, in general, should be smaller than the difference in averages between the test and concurrent placebo that superior trials try to detect.

Although the equivalence limits for average bioequivalence required by the FDA are well accepted and established, selection of the equivalence limits for assessing similarity is always controversial and remains a challenge in other areas.^[27,28] If the selected equivalence limits are too narrow, it is extremely difficult to conclude equivalence although the difference between them is of no clinical significance. On the other hand, if the chosen equivalence limits are very wide, then it is easy to declare the two drugs with a clinically meaningful difference to be equivalent.

In general, the equivalence limits depend on the response of the reference drug. For example, Huque and Dubey^[4] have proposed some equivalence limits for binary data such as eradication rate for antibiotics. They suggested that the equivalence limits be tighter for higher reference response rates. Suppose that the response rate was 75% from two adequate, well-controlled studies for approval of the reference drug. The equivalence limits suggested by Huque and Dubey^[4] is $\pm 20\%$. The sample size can also be determined based on $\pm 20\%$ equivalence limits. However, when the current equivalence trial yields a reference response rate of 85%, should the equivalence limits be

Table 1 Comparison of the Results by Different Procedures for Assessing Equivalence with a Known Symmetric Limit of 0.2

Observed difference	90% (C.I.)	H _{0E}	H _{0L}	H _{0U}	Two-sided equivalence
0.00	(−0.10, 0.10)	Fail to reject	Reject	Reject	Yes
0.00	(−0.25, 0.25)	Fail to reject	Fail to reject	Fail to reject	No
0.05	(0.02, 0.08)	Reject	Reject	Reject	Yes
0.10	(−0.02, 0.22)	Fail to reject	Reject	Fail to reject	No

H_{0E} is the null hypothesis for equality. (From Chow and Liu^[9].)

changed to $\pm 15\%$ as suggested by Huque and Dubey?^[4] Is the sample size calculated with the limits of $\pm 20\%$ large enough to provide sufficient power for the limits of $\pm 15\%$?

These questions reveal the issues that the equivalence limits based on the reference responses from any previous studies are not internally valid. Therefore the equivalence limits may be chosen based on the reference response obtained concurrently within the same equivalence trial for internal validity. In this case, the lower and upper equivalence limits in the interval hypothesis Eq. (2), however, are no longer fixed known quantities but random variables. The formulation for interval hypothesis should be reformulated as

$$H_a : L < \mu_T / \mu_R U \quad (4)$$

where $0 < L < 1 < U$.

The interval hypothesis in Eq. (4) implies that the two drugs are equivalent in average if the ratio of averages is between L and U . Logarithmic transformation of Eq. (4) reformulates the interval hypothesis from ratio to the difference as

$$H_a : \ln(L) < \ln(\mu_T) - \ln(\mu_R) < \ln(U)$$

where $\ln$ denotes the natural logarithm and $\ln(L) < 0 < \ln(U)$.

If the test and reference drug products are equivalent, both of them could be better than placebo or they could be worse than placebo. Evaluation of equivalence through the interval hypothesis in Eq. (4) therefore does not necessarily establish efficacy of the test drug product without a concurrent placebo control. Lack of assay sensitivity is one of the serious issues for active controlled trial. For more discussion, see Wang et al.^[29]

For assessment of average bioequivalence between a generic and a reference formulation, most regulatory agencies such as the FDA and EC request that PK responses such as AUC or $C_{\max}$ be analyzed on the logscale with $L = 80\%$ and $U = 125\%$, that is, $\ln(L) = -0.2231$ and $\ln(U) = 0.2231$.

On the other hand, if data are analyzed on the original scale, the equivalence limits in Eq. (2) depend on the observed reference mean for internal validity. Suppose that in Eq. (2) $L = f\mu_R$ and $U = g\mu_R$, then the two one-sided hypotheses corresponding to Eq. (2) can then be formulated as

$$\begin{aligned} H_{0L} : \mu_T - (1-f)\mu_R &\leq 0 \\ \text{vs.} \\ H_{aL} : \mu_T - (1-f)\mu_R &> 0, \\ \text{and} \\ H_{0U} : \mu_T - (1-g)\mu_R &\leq 0 \\ \text{vs.} \\ H_{aU} : \mu_T - (1-g)\mu_R &> 0. \end{aligned} \quad (5)$$

Consequently, the two one-sided tests procedure can be constructed based on the estimates for $\mu_T - (1-f)\mu_R$ and

$\mu_T - (1-g)\mu_R$ and their estimated standard errors. However, currently, the two one-sided tests procedure for average are performed with estimated equivalence limits based on the observed reference mean as the true unknown fixed quantities without taking into consideration the variability of estimated equivalence limits. Liu and Weng^[30] have shown that for the data obtained from the 2×2 crossover design, the traditional application of the two one-sided tests procedure cannot control the probability of type I error. When the correlation between the two responses from the same patient approaches 1, the consumer's risk goes to 50%. They proposed a modified two one-sided tests procedure based on the two one-sided hypotheses in Eq. (5), which adequately controls type I error rate at the nominal level.

POPULATION BIOEQUIVALENCE

As demonstrated above, average bioequivalence does not guarantee that the generic and reference product can be used interchangeably. In general, interchangeability between the generic product and the reference product can be classified as prescribability and switchability. "Prescribability" is referred to as the physician's choice, for prescribing a drug for new patients, between an innovative product and a number of its generic copies that have been shown to be bioequivalent to the innovative product.^[11] On the other hand, "switchability" is related to the switch from a drug such as an innovative product or a generic drug to an alternative drug such as a generic copy of a brand-name drug or another generic copy of the same innovative drug product within the same patient whose concentration of the drug has been titrated to a steady, efficacious, and safe level. To ensure switchability, the equivalence between drug products must be demonstrated within each individual. This concept is referred to as "individual bioequivalence."

For evaluation of population bioequivalence, as mentioned above, under normality assumption, equivalence in both average and variability is required. One approach is to conclude population bioequivalence at the α significance level if both the null hypothesis for average in Eq. (1) and that for variability in Eq. (4) are rejected at the α significance level.^[21] This disaggregate procedure is another application of the union-intersection principle. As a result, although it is a size α test, it can be very conservative. The FDA issued guidance on January 2001 on statistical approaches to establish bioequivalence. The guidance suggested using the following mixed-scaling aggregate criterion for assessment of population bioequivalence based on the log-scale of AUC or $C_{\max}$:

$$\theta = [(\mu_T - \mu_R)^2 + (\sigma_{TT}^2 - \sigma_{TR}^2)] / \max(\sigma_{TR}^2, \sigma_{TO}^2) \quad (6)$$

where σ_{TT}^2 is the total variance (sum of intrasubject and intersubject variability) of the test formulation, σ_{TR}^2 is the

total variance of the reference formulation, and σ_{TO}^2 is the specified constant total variance.

If $\sigma_{TR}^2 > \sigma_{TO}^2$, the aggregate criterion in Eq. (6) is scaled by the total reference variability. It is then referred to as the reference-scaled criterion. When σ_{TR}^2 is smaller than σ_{TO}^2 , the guidance proposes that σ_{TR}^2 in the denominator of Eq. 6 is replaced by σ_{TO}^2 . The resulting criterion is then referred to as constant-scaled criterion. Population bioequivalence is concluded if θ is smaller than some pre-specified upper equivalence limit θ_p . The corresponding hypothesis can be written as

$$H_0: \theta \geq \theta_p \quad \text{vs.} \quad H_a: \theta < \theta_p \quad (7)$$

The FDA guidance suggests that sponsors or applicants contact the FDA for further information about σ_{TO}^2 and θ_p if the sponsors or applicants wish to use the population bioequivalence criterion. The distribution of the estimator of θ is quite complicated. The confidence interval approach to test hypothesis Eq. (7) for evaluation of bioequivalence requires the use of the bootstrap procedure. As a result, the FDA guidance suggests using the following linearized criterion:

$$\eta = [(\mu_T - \mu_R)^2 + (\sigma_{TT}^2 - \sigma_{TR}^2)] - \theta_p \max(\sigma_{TR}^2, \sigma_{TO}^2) \quad (8)$$

The corresponding hypothesis is given as

$$H_0: \eta \geq 0 \quad \text{vs.} \quad H_a: \eta < 0 \quad (9)$$

The FDA guidance recommends the method proposed by Hyslop et al.^[31] to derive close-form upper approximate confidence limit for η . The population bioequivalence is concluded at the α significance level if the upper $(1 - \alpha)100\%$ confidence limit for η is smaller than 0 provided the point estimate of μ_T/μ_R based on the geometric mean is with 0.8 and 1.25. From Eq. 6, the aggregate criterion proposed in the FDA guidance is based on the difference in average bioavailability and difference in total variability scaled by the reference total variability. As a result, crossover design is no longer required for assessment of population bioequivalence. A two-group parallel design with a single PK response from each subject will suffice for evaluation of population bioequivalence.

Individual bioequivalence is one of the approaches used to assess bioequivalence between the generic and reference listed drug recommended by the FDA guidance.^[32] Aggregate referenced-scaled and constant-scaled criteria similar to those for population bioequivalence are also proposed for evaluation of individual bioequivalence. The criterion for individual bioequivalence is scaled by the reference intrasubject variability. The constant-scaled criterion is selected if the reference intrasubject variability is smaller than 0.04. There are many unresolved issues for the aggregate criterion such as masking effects, unknown bias and power function, inference for second moments, two-stage

procedure, interpretation of results, and others. These issues will be addressed in detail in the entry *Individual Bioequivalence*.

Ethnic Factors

Melody H. Lin

Office for Human Research Protections, Department of Health and Human Services,
Rockville Maryland, U.S.A.

Helen McGough

Human Subjects Division, University of Washington, Seattle, Washington, U.S.A.

Abstract

Ethnicity may be used to refer to “racial” or “genetic” differences between groups of people. It may be used to refer to behavioral and social differences, such as language, religion, dress, mode of making a living, or kinship patterns. This entry addresses the factors associated with how the results of a clinical study translate across ethnic borders.

Keywords: Ethnicity; Extrinsic; Intrinsic.

INTRODUCTION

Can efficacy and safety data about an experimental drug or device from a trial conducted in one region be extrapolated to other regions? Will governmental regulatory bodies accept data collected in a region other than its own in support of drug or device registration? Will the health care environment in one region respond in the same manner to a new drug or device as in another region? Questions such as these often result from the issue of how important ethnic factors are in determining the safety, efficacy, dosage, and therapeutic regimen of a new drug or device.

DEFINING ETHNIC FACTORS

Ethnicity is a concept that is defined in many different ways and to meet different objectives. *Ethnicity* may be used to refer to “racial” or “genetic” differences between groups of people. It may be used to refer to behavioral and social differences, such as language, religion, dress, mode of making a living, or kinship patterns. It may also refer to differences in climate and environmental and occupational exposures. The problems inherent in the use of this term are reflected in the current dispute in the United States about how to categorize its citizens into ethnic groups. Should all Spanish-speaking people be labeled “Hispanic”? Such a category would lump together people from as disparate cultural origins as Spain, Argentina, and Cuba. Should the term “African American” apply to a sixth-generation descendant of West Africans brought to North America over 200 years ago as well as to a recent immigrant from Nigeria or South Africa?

In the conduct of clinical trials, the concept of *ethnicity* may also be used in a variety of ways. Ethnic factors may relate to differences in metabolism between groups of people, differences in health care practices, and differences in response to pain, for example. Ethnic factors may have an impact not only on the safety and efficacy of a new drug or device, but also on the acceptance the drug or device is likely to have—how well it will fit in to a particular population’s lifestyle, budget, and health care practices.

The International Conference on Harmonization (ICH) has proposed a distinction between what it describes as the physiologic aspects of ethnicity (*intrinsic* ethnic factors) and the cultural and environmental aspects of ethnicity (*extrinsic* ethnic factors). Under *intrinsic* factors, the ICH Guidelines include genetic makeup of a population, similarities in height, body mass and composition, and organ dysfunction. Under *extrinsic* factors, the ICH Guidelines include environmental factors, such as climate, pollution, and altitude, and cultural or behavioral factors, such as diet, religion, the use of drugs (including tobacco) and alcohol, and indigenous health care systems.

This is a useful way to categorize ethnic factors. However, such a categorization may gloss over the importance of considering the interrelationships between intrinsic and extrinsic ethnic factors. As in many disease syndromes, such as alcoholism, diabetes, heart disease, and mental illnesses, extrinsic and intrinsic factors may have to work together to potentiate the emergence of the disease itself. Genetic predisposition may not inevitably lead to disease, but genetic predisposition plus environmental exposure may make disease development certain.

WHY IS IT IMPORTANT TO INCLUDE ETHNIC FACTORS IN DESIGNING SAFE AND EFFECTIVE TRIALS?

There are at least two ways that ethnic factors influence the conduct of clinical trials. One is from the point of view of study design and implementation. The other is from the point of view of the utility of the data collected. Ethnic factors must be considered in the design and implementation of the trial in order to produce useful data for purposes of registration. But ethnic factors must also be considered before the decision to conduct a trial in a foreign region is made. What are some of the reasons for the importance of considering ethnic factors in the conduct of clinical trials?

1. Unless these factors are considered, we will not have an adequate understanding of the relationship among culture, race, environment, and disease in terms of pathobiology, etiology, diagnosis, progression, treatment, outcomes, risk reduction, and drug delivery. These issues will play an important role in the methodological design of a clinical trial.
2. Ethnicity is often a marker of other kinds of distinguishing features among people around the world. Ethnicity may mark disparities in levels of health (malnutrition, hopelessness) or in the transfer of information about health and disease (access to care, types of care available, attitudes toward risk reduction). Ethnic factors may determine whether a drug or device will have market acceptance once it is approved. These are issues to be considered before registration decisions are made.

IMPLICATIONS FOR THOSE CONDUCTING CLINICAL TRIALS IN FOREIGN REGIONS

Let us assume that the decision has been made to conduct a trial in a foreign region. This decision initiates special considerations, responsibilities, and opportunities for the researcher as well as for the region in which the study will be conducted.

1. *Involvement of local researchers and research staff, including social scientists such as anthropologists, sociologists, psychologists, and epidemiologists in the trial design as well as implementation.* Knowledgeable researchers can improve the way trials are conducted in many important ways, including issues of recruitment, retention, adherence, and loss to follow-up. Understanding regional attitudes toward medicine, for example, may improve the design of a trial of a new drug by recognizing potentially confounding variables, such as the use of traditional medicines,

diet, and eating and drinking patterns. Providing incentives that are culturally appropriate may improve retention and adherence. Recognizing mobility patterns and anticipating them may result in smaller losses to follow-up.

2. *Designing pharmacokinetic and pharmacodynamic studies tailored to what is known about the population in which the trial will be conducted.* It is important to conduct clinical trials in foreign regions that take into account such ethnic factors as differences in metabolism, dose response, and genetic differences. These factors may affect the levels at which unacceptable toxicity is reached or efficacy rates. Differences in the levels of clearance enzymes, lipids, fibrinogen, and glucose, for example, may have important implications for the extrapolation of data from one region to another. Without accurate information, the human subjects of such trials could be put at unnecessary risk, and the resulting data may be misunderstood and useless.
3. *Designing dose-response and efficacy studies to include well-defined endpoints and disease definitions that are recognized by the local researchers and by the population members.* Ethnic factors may play a role in how *health* and *wellness* are defined. For example, the degree to which the risk of impotence is acceptable may affect the success or failure of a trial of an experimental prostate cancer drug.
4. *Evaluating clinical trials conducted in the population of drugs in the same class as the experimental drug, or similar devices, or of different dosages in a determination of whether or not a new trial must be conducted.* Before a decision to conduct a trial in a foreign region is made, researchers must determine if ethnic factors affect a new drug's safety and efficacy. It may be that trials of drugs in the same class as the experimental drug have shown no outcome or toxicity differences between two regions. It may be that similar dosages and therapeutic regimens have been similar among the two populations. It may not be necessary to conduct the trial at all. On the other hand, it may be that no trials of similar drugs, dosages, or therapeutic regimens have been conducted, or that previous trials have produced dissimilar results. In this case, if the decision to seek registration in a foreign region has been made, it is important to conduct carefully controlled safety and efficacy trials among that region's population.

IMPLICATIONS FOR HUMAN SUBJECTS REVIEW

Clinical trials in foreign regions may pose special challenges for the ethical review boards charged with the

protection of human subjects, especially as global development of new drugs and devices expands and matures. The diversity and breadth of clinical trials will increase, and the expertise required of ethical review boards will also expand. What are some of the steps that ethical review boards can take to prepare for these new challenges?

1. *Learn the ICH's good clinical practices (GCP) with regard to Institutional Review Board (IRB) or Institutional Ethics Committee (IEC) guidance.* The guidance published in the Federal Register (June 10, 1998) outlines the important conditions and procedures that are required to conduct ethical reviews of clinical trials.
2. *Require local ethical review of the clinical trial and request documentation of its findings.* It will become even more important than it is today to make sure that clinical trials receive ethical review in the regions in which they are conducted. This may result in a multiplicity of boards reviewing the same trial from quite different perspectives. It will become incumbent upon each board to make sure it maintains open communication with the researcher as well as with the other ethical review boards considering the same trial. Each review board may request documentation of the local region's determination with regard to a particular trial before making its own decision. Not only is requesting documentation helpful to the boards reviewing a study, it also makes sure that the population of the region plays a part in determining whether or how the trial is conducted.
3. *Involve experts who can contribute information on ethnic factors in the consideration of a new clinical trial.* Traditionally, ethical review boards have been composed primarily of medical personnel who are experts in certain medical traditions. It will be important to expand the membership of these boards to incorporate less traditional members, including citizens of the region in which the trial will be conducted as well as experts in understanding and evaluating the impact of ethnic factors on the conduct of trials. The education involved in expanding membership is a two-way process. Conventional board members will need to learn more about ethnic factors, and the new members will have to learn about the ethics of research with human subjects.

BARRIERS TO THE ETHICAL CONDUCT OF TRIALS IN FOREIGN POPULATIONS

Time

In an increasingly competitive marketplace, speed is of the essence in bringing a drug to approval. Conducting trials in foreign populations will increase the time this process takes.

Budget

Conducting trials in foreign populations may be even more expensive than conducting trials in the sponsor's home country or in the country that is the primary marketing target.

Communication

Dealing with researchers and research subjects who are ethnically different from one another and from the sponsor may create problems leading to trials that are conducted poorly, are at variance with the protocol, and result in incomplete or inadequate data. Miscommunication may result not only from language differences but also from religious, political, or other "extrinsic" ethnic factors.

Stigmatization

Sponsors and researchers may need to work to overcome initial distrust and fear of "foreign" research and of researchers conducting trials in their regions. Education of the region's population and learning from the region may be a slow, and therefore costly, process.

CONCLUSION

Despite these barriers, the ethical conduct of clinical trials in all regions of the world is now an easier goal to accomplish than ever before. Increasing agreement among different regions on the ethical principles necessary to conduct high-quality trials while protecting human subjects will lead to heightened consistency and cooperation among ethical review boards. The basic ethical principles of respect, beneficence, and justice are grounded in the concept of regional review. Regional ethical review boards best evaluate ethnic factors. Cooperation between these boards and researchers will lead to safer, more efficient clinical drug trials and delivery of high-quality health care to humans everywhere.

Expiration Dating Period

Annpey Pong

Merck Research Laboratories, Summit, New Jersey, U.S.A.

Abstract

The expiration dating period (or shelf-life) of a drug product is defined as the time interval that the characteristics of the product will remain within the approved specification limits after manufactured. This entry focuses on the methods of determining the expiration dating period of a drug product and the regulatory requirements that influence this decision.

Keywords: Batch-to-batch; Direct method; Inverse method; Shelf-life.

INTRODUCTION

The Food and Drug Administration (FDA) requires that for every drug product on the market, an expiration dating period must be indicated on the immediate container label. The *expiration dating period* (or shelf-life) is defined as the time interval that the characteristics of the drug product will remain within the approved specification limits after manufactured.

For determination of the expiration dating period of a given batch of a drug product, as indicated in the FDA stability guideline in 1987,^[1] the expiration dating period can be estimated as the time at which the 95% one-sided lower (upper) confidence bound for the mean degradation curve intersects the approved lower (upper) specification limit if the drug characteristic is expected to decrease (increase) with time in a linear fashion (see Fig. 1). If the relationship between the drug characteristic of interest and time is not linear, it may be linearized using an appropriate transformation (e.g., a linear, quadratic, or cubic function on an arithmetic or logarithmic scale).

It should be noted that the term *shelf-life* and *expiration dating period* are often used interchangeably in the literature. In fact, the *expiration dating period* is the term used in the FDA's guideline for the labeled shelf-life, while the *shelf-life* is a broad name used in drug research and development. The true shelf-life is defined as the point of intersection between true degradation curve and the specification limit of a drug product.

REGULATORY REQUIREMENTS

To assure the integrity of commercial drugs, the U.S. Pharmacopeia (USP) included the first clause regarding drug shelf-life in 1975. In 1984, the FDA first required stability testing. To determine the expiration dating period,

a stability study is usually conducted to characterize the degradation of the drug product. The stability testing will provide evidence on how the quality of a drug product varies with time under the influence of a variety of environmental factors (e.g., temperature, humidity, and light) and to establish expiration dating period appropriate for the drug product. That is, stability studies will provide certain assurance or confidence that the drug product meets the standards for expected characteristics of identity, strength, quality, and purity prior to the expiration date.

The specific requirements on statistical design and analysis of stability studies for human drugs and biologics were not available until the FDA stability guideline issued in 1987. In 1993, the International Conference on Harmonization (ICH) issued guidelines^[2] on stability based on a strong industrial interest in international harmonization of regulatory requirements for marketing in the European Community (EC), Japan, and the United States. The six ICH member representatives are the European Commission, the European Federation of Pharmaceutical Industry Associations, the Japanese Ministry of Health and Welfare, the Japanese Pharmaceutical Manufacturers Association, the FDA, and the U.S. Pharmaceutical Manufacturers Association. At the same time, the World Health Organization (WHO) also published draft guidelines for stability. After ICH deliberations led to several stability guidelines in the period from 1994–1997, the draft *FDA Guideline on Stability Practice* was published in June 1998. This draft FDA guideline^[3] incorporates the texts of four ICH documents, which were revised and expanded from the 1987 stability guideline. There was no specific change in statistical principles in analyzing stability data in this draft guideline compared to the 1987 stability guideline. Note that the most recent issue refers to ICH Q1A(R2) *Stability Testing of New Drug Substances and Products* in 2003.^[4]

Generally, there are different criteria for acceptable levels of stability with respect to chemical, physical,

Fig. 1 Determination of drug expiration dating period

Table 1 Drug Characteristics for Different Dosage Forms

Dosage form	Drug characteristics
Tablets	appearance, friability, hardness, color, odor, moisture, strength, dissolution
Capsules	strength, moisture, color, appearance, shape, brittleness, dissolution
Emulsions	appearance, color, odor, pH, viscosity, strength
Oral solution and suspensions	appearance, strength, pH, color, odor, redispersibility, dissolution, clarity
Oral powder	appearance, pH, dispersibility, strength
Metered dose ophthalmic preparations	strength, delivered dose per actuation, number of metered doses, color, clarity, particle size, loss of propellant, pressure, valve corrosion, spray pattern
Topical and ophthalmic preparations	appearance, clarity, color, homogeneity, odor, pH, redispersibility, consistency, particle size distribution, strength, weight loss
Small-volume parenterals	strength, appearance, color, particulate matter, pH, sterility, pyrogenicity
Large-volume parenterals	strength, appearance, color, clarity, particulate matter, pH, volume, extractables, sterility, pyrogenicity
Suppositories	strength, softening, range, appearance, dissolution

microbiological, therapeutic, and toxicological characteristics of drug products.^[5] Table 1 gives a list of drug characteristics for different dosage forms that should be evaluated in a stability study. The strength of a drug product is defined as either (i) the concentration of the drug substance or (ii) the potency, i.e., the therapeutic activity of the drug product which can be determined by an appropriate laboratory test or by an adequately developed and controlled clinical data. For the analysis of stability data, the FDA requires that percent of label claim, not percent of initial average value, be used as the primary variable for strength. In practice, the determination of drug expiration

Table 2 Regulatory Differences

Regulatory factor	FDA	EC/Japan
Drug product commerce	Regulate drug products for U.S. and international commerce	Focused on intranational commerce
Specifications Strength (assay)	90–110% label claim	95–105% (release and shelf specifications) in many cases. Must provide justification for 90–110%
Labeling	Controlled room temperature (CRT)	Room temperature
Definition of temperature	15–30°C, USP-PF proposal	EC, defined as 15–25°C Japan, defined as 1–30°C
Expiration dating period	Based on statistical evaluation of three lots on stability studies-assay/impurities Physical attributes (e.g., hardness, moisture, dissolution, appearance)	Based on summary of at least two lots—no statistical requirement
Container/closure	Actual marketing package	No well-defined requirements

dating period is usually based on the primary drug characteristic of interest such as strength or potency rather than other drug characteristics in most stability studies.

The ICH guideline is similar to the FDA guideline in principle. However, the ICH guideline provides a general indication on the requirements for stability testing, but leaves sufficient flexibility to encompass the variety of different situations and characteristics of the materials being evaluated.^[6] To compare the regulatory difference among the United States, European Community, and Japan, Kumkumian^[7] summarized the results shown in Table 2.

The stability testing for post-approval changes is also addressed in the FDA draft guideline.^[4] In the past, all post-approval changes were considered together and required extensive stability documentation. With the publication of the Scale-Up and Post-Approval Change for Immediate Release/Modified Release (SUPAC-IR/MR) solid oral dosage forms guideline, this approach was modified. For example, the stability commitment to support post-approval changes could rely on the first one or three production batches and annual batches thereafter on long-term stability studies. If the data give no reason to believe that the proposed change will alter the stability of the drug product, the previously approved shelf-life can be used.

Statistical Methods

To determine the drug expiration dating period, three methods are illustrated. The first method is recommended in the FDA's guideline, and the other two methods, direct method and inverse method, were proposed by Shao and Chow.^[8] The completed information on statistical design and analysis of stability studies can be found in Chow, 2007.^[9]

FDA's Approach

In the guideline, assuming the drug characteristic decreases linearly with time, then the following linear regression model is used.

$$y_j = \alpha + \beta t_j + e_j, \quad j = 1, \dots, n \quad (1)$$

where y_j is the assay result (percent of labeled claim) at time t_j , α and β are the intercept and slope, respectively, t_j 's are the sampling time points selected in the stability study, e_j 's are random errors which are independent and identically distributed as $N(0, \sigma^2)$.

The commonly used method for the estimation of α , β , and σ^2 is the method of ordinary least squares (OLS), which yields $\hat{\alpha} = \bar{y} - \hat{\beta}\bar{t}$, $\hat{\beta} = S_{TY}/S_{TT}$, $\hat{\sigma}^2 = S_{YY} - \hat{\beta}S_{TY}/n - 2$ where

$$\begin{aligned} \bar{t} &= \frac{1}{n} \sum_{j=1}^n t_j, \quad \bar{y} = \frac{1}{n} \sum_{j=1}^n y_j, \\ S_{TT} &= \sum_{j=1}^n (t_j - \bar{t})^2, \quad S_{TY} = \sum_{j=1}^n (t_j - \bar{t})(y_j - \bar{y}), \\ S_{YY} &= \sum_{j=1}^n (y_j - \bar{y})^2 \end{aligned}$$

At a specific time point, $t = t_0$, the least square estimate of mean degradation is given by $y(t_0) = \hat{\alpha} + \hat{\beta}t_0$ with the estimated variance $\hat{V}(y(t_0)) = \hat{\sigma}^2 \left[\frac{1}{n} + \frac{(t_0 - \bar{t})^2}{S_{TT}} \right]$.

The 95% lower confidence limit of the mean degradation line is given by $L(t_0) = \hat{\alpha} + \hat{\beta}t_0 - t_{.95}(n-2) \left[\hat{\sigma}^2 \left[\frac{1}{n} + \frac{(t_0 - \bar{t})^2}{S_{TT}} \right] \right]^{\frac{1}{2}}$ where $t_{.95}(n-2)$ is the 95th percentile of the central t distribution with $n-2$ degrees of freedom. Consequently, the expiration dating can be obtained as the minimum of the two solutions of t_0 from the following quadratic equation:

$$\left[\eta - (\hat{\alpha} + \hat{\beta}t_0) \right]^2 = t_{.95}(n-2) \hat{\sigma}^2 \left[\frac{1}{n} + \frac{(t_0 - \bar{t})^2}{S_{TT}} \right] \quad (2)$$

where η is the specification limit. Therefore, the shelf-life estimator based on FDA's approach is the solution of Eq. (2), i.e.,

$$\hat{\theta}_F = \left[\hat{\beta}^2 - C_n \right]^{-1} \left[(\eta - \hat{\alpha})\hat{\beta} + B_n - \sqrt{\left[(\eta - \hat{\alpha})\hat{\beta} + B_n \right]^2 - (\hat{\beta}^2 - C_n) \left[(\eta - \hat{\alpha})^2 - A_n \right]} \right]$$

where

$$\begin{aligned} A_n &= \hat{\sigma}^2 t_{.95}^2 (n-2) \left(\frac{1}{n} + \frac{\bar{t}^2}{S_{TT}} \right), \\ B_n &= -\frac{\bar{t} \hat{\sigma}^2 t_{.95}^2 (n-2)}{S_{TT}}, \quad C_n = \frac{\hat{\sigma}^2 t_{.95}^2 (n-2)}{S_{TT}}. \end{aligned}$$

Direct Method

In the direct method, the shelf-life is determined by an approximate ($n \rightarrow \infty$ or $\sigma \rightarrow 0$) 95% lower confidence bound for the true shelf-life of $\theta = (\eta - \alpha)/\beta$, which is

$$\hat{\theta}_D = \frac{\eta - \hat{\alpha}}{\hat{\beta}} - \frac{\hat{\sigma} z_{.95}}{|\hat{\beta}|} \left(\frac{1}{n} + \frac{1}{S_{TT}} \left(\frac{\eta - \hat{\alpha}}{\hat{\beta}} - \bar{t} \right)^2 \right)^{\frac{1}{2}} \quad \text{where } z_{.95} \text{ is the 95th percentile of the standard normal distribution.}$$

This is based on the asymptotic theory that

$$\left(\frac{\eta - \hat{\alpha}}{\hat{\beta}} - \theta \right) \left(\frac{\hat{\sigma}}{|\hat{\beta}|} \sqrt{\frac{1}{n} + \frac{1}{S_{TT}} \left(\frac{\eta - \hat{\alpha}}{\hat{\beta}} - \bar{t} \right)^2} \right)^{-1} \rightarrow N(0,1) \text{ in law}$$

Thus, an asymptotic lower confidence bound for θ is defined as $\hat{\theta}_D = (\eta - \hat{\alpha}/\hat{\beta}) - 1.645s$ where $\hat{\theta}_D$ is the estimator of shelf-life from the direct method, and s is an estimated asymptotic standard deviation of $\eta - \hat{\alpha}/\hat{\beta}$.

Inverse Method

In this method, the shelf-life estimator is obtained based on the inverse regression model, which is defined as below:

$$t_j = \alpha^* + \beta^* y_j + e_j^*, \quad j = 1, \dots, n \quad (3)$$

The shelf-life estimator $\hat{\theta}_I$ based on the inverse method is the 95% lower confidence bound for $\alpha^* + \beta^*\eta$, because the true shelf-life is the t -value when the mean of $y = \eta$. By considering an ordinary linear regression model in Eq. (3), the following estimators are obtained $\hat{\alpha}^* = \bar{t} - (S_{TY}/S_{YY})\bar{y}$, $\hat{\beta}^* = S_{TY}/S_{YY}$.

Also, the estimator for the variance of $\hat{\alpha}^* + \hat{\beta}^*\eta$ is

$$\frac{1}{n-2} \left(S_{TT} - \frac{S_{TY}^2}{S_{YY}} \right) \left(\frac{1}{n} + \frac{(\eta - \bar{y})^2}{S_{YY}} \right) = \hat{\sigma}^2 \frac{S_{TT}}{S_{YY}} \left(\frac{1}{n} + \frac{(\eta - \bar{y})^2}{S_{YY}} \right)$$

Therefore, the shelf-life estimator based on the inverse method is

$$\hat{\theta}_l = \bar{t} + \frac{S_{TT}}{S_{rr}}(\eta - \bar{y}) - \hat{\sigma}_{t_{.95}}(n-2) \sqrt{\frac{S_{TT}}{S_{rr}} \left(\frac{1}{n} + \frac{(\eta - \bar{y})^2}{S_{rr}} \right)}.$$

These three methods were further compared based on their asymptotic biases and mean squared errors of the true shelf-life.^[8] It is concluded that the FDA's method is slightly better when σ is large, and the direct method is better when σ is small according to the bias, mean squared error of $\hat{\theta}_p$, $\hat{\theta}_l$, and $\hat{\theta}_r$, and coverage probability from the simulation result. The coverage probability is the proportion of times the confidence intervals cover the true shelf-life in a simulation study. In general, the inverse method is too conservative unless σ is very small.

Practical Issues

Batch-to-Batch Similarity

The FDA guideline requires that a stability study be conducted by testing at least three batches, and the batch similarity be examined by the preliminary test to verify the equality of slopes and intercepts of all batches. The guideline also indicates that the preliminary tests for the equality of slopes and equality of intercepts be performed at the 0.25 level of significance, which was suggested by Bancroft.^[10] If the preliminary tests for the equality of slopes and the equality of intercepts are not rejected at the 0.25 level of significance, then the common slope and intercept are estimated on the pooled stability data from all batches. Note that as pointed out by Ruberg and Stegeman,^[11] the use of the significance level of 0.25 for assessing batch-to-batch similarity for poolability (or combinability) might penalize good batches in drug shelf-life estimation. On the other hand, if preliminary tests are rejected at the 0.25 level of significance, the minimum of shelf lives obtained from individual batches is considered as the drug shelf-life.

The disadvantage of the minimum approach is too conservative and does not consider the batch-to-batch variation. Chow and Shao^[12,13] pointed out that the presence of batch-to-batch variation has an impact on the determination of shelf-life. Therefore, it is of interest to estimate the batch-to-batch variation. Chow and Wang^[14] indicated that the estimated batch variation can be used to determine the homogeneity of degradation rates for pooling data from a batch, and evaluate whether or not a desired labeled shelf-life can be reached. Because the primary goal of a stability study is to apply the established shelf-life to all future production batches, several approaches for the determination of shelf-life with random batches have been proposed.

Shao and Chow^[15] proposed a method that ensures that future batches have longer shelf lives than the labeled shelf-life with a given statistical assurance. According to Sun et al.,^[16] the individual expiration dating period proposed

in Shao and Chow^[15] is an asymptotically normally distributed random variable.

Two-Phase Shelf-Life Estimation

In practice, the drug products may be stored under different temperatures in stability testing. For example, the drug product may require (i) 24 months at -20°C followed by either 1 month at 5°C and 2 days at 25°C , or (ii) 24 months at -20°C followed by 2 weeks at 5°C and 1 day at 25°C .^[17] These types of drug products are called the frozen drug products. In stability study, the drug shelf-life of frozen drug products is determined by a two-phase stability study; that is, each phase has its own stability testing based on the different temperatures. Mellon^[18] suggested analyzing each phase separately to obtain a combined expiration dating and provided a number of approaches for the analysis of frozen drug products. However, this method does not account for the fact that the expiration dating at the second phase would depend on the first phase. Using the changing point which occurs at the time point of the 95% lower confidence limit of the mean degradation curve at the first phase that intersects the approved lower specification limit as the expiration dating was considered by Shaban^[19] and Hinkley.^[20] Furthermore, Shao and Chow^[21] proposed a method by using a two-phase regression analysis to determine the drug shelf-life of frozen drug products.

Shelf-Life Estimation with Discrete Responses

In the current stability guidelines, the expiration dating period is determined based on the mean degradation curve of continuous response (e.g., potency) over time. However, both the FDA and ICH stability guidelines also require that some other discrete characteristics such as color and hardness should also be considered when performing stability studies, but no written guideline to determine the shelf-life for discrete responses. Chow and Shao^[22] proposed two shelf-life estimators that are applicable to all future batches when the stability data are discrete. The first method is suitable for binary data without batch-to-batch variation, and the second method is useful for the random batches. Both methods are summarized below.

Binary Data Without Batch-to-Batch Variation

Let y_{ij} be the binary response of the i th batch at some time points n_i , assuming y_{ij} 's are independent. Then the following model in Eq. 4 is followed:

$$\begin{aligned} E(y_{ij}) &= \frac{e^{\beta^T x_{ij}}}{1 + e^{\beta^T x_{ij}}}, \quad i = 1, \dots, k, \\ \text{Var}(y_{ij}) &= \frac{e^{\beta^T x_{ij}}}{1 + e^{\beta^T x_{ij}}} \left(1 - \frac{e^{\beta^T x_{ij}}}{1 + e^{\beta^T x_{ij}}} \right), \quad j = 1, \dots, n_i \end{aligned} \quad (4)$$

where x_{ij} is a p -vector of covariates, such as time points or bottle size; β^T is the transpose of β , which is a p -vector of unknown parameters. The proposed shelf-life estimator is $\hat{t}^* = \inf\left(t : L(t) \leq \frac{1+e^\eta}{e^\eta}\right)$ which satisfies $P_Y(\hat{t}^* > t^*) \leq 5\%$ where $\hat{t}^*$ is an approximate 95% lower confidence bound for the true shelf-life t^* , P_Y is the approximate probability which is determined based on the distribution of $\hat{\beta}$, and $L(t) = \hat{\beta}^T x(t) - z_{0.95} \times \sqrt{x(t)^T \hat{V} x(t)}$ where $z_{0.95}$ is the 95th percentile of the standard normal distribution; $\hat{\beta}$ is obtained by solving the following equation $\sum_{i=1}^k \sum_{j=1}^{n_i} x_{ij} \left(y_{ij} - \frac{e^{\beta^T x_{ij}}}{1 + e^{\beta^T x_{ij}}} \right) = 0$ and $\hat{V}$ is estimated by

$$\hat{V} = \left[\sum_{i=1}^k \sum_{j=1}^{n_i} x_{ij} x_{ij}^T \frac{e^{\hat{\beta}^T x_{ij}}}{1 + e^{\hat{\beta}^T x_{ij}}} \left(1 - \frac{e^{\hat{\beta}^T x_{ij}}}{1 + e^{\hat{\beta}^T x_{ij}}} \right) \right]^{-1}$$

Random Batches

Assuming k batches be the random sample, then β_i 's in Eq. (4) are random effects. Therefore, a mixed-effect model with conditional expectation and variance of y_{ij} given the random effect β_i is considered. The true shelf-life is a random variable, which is given by $t_{\text{future}}^* = \inf(t : \beta_{\text{future}}^T x(t) \leq 1 + e^\eta / e^\eta)$. The proposed shelf-life estimator for t_{future}^* is $\hat{t}_{\text{future}}^* = \inf(t : L(t) \leq 1 + e^\eta / e^\eta)$ where $L(t) = \hat{\beta}^T x(t) - \rho_{0.95}(k) \sqrt{v(t)/k}$ with

$$v(t) = x(t)^T \left[\frac{1}{k-1} \sum_{i=1}^k (\hat{\beta}_i - \hat{\beta})(\hat{\beta}_i - \hat{\beta})^T \right] x(t)$$

$\hat{\beta}_i$ is the maximum likelihood estimator of β_i , and $\hat{\beta}$ is the average of $\hat{\beta}_i$ for i from 1 to k . Also, $\rho_{0.95}(k)$ satisfies $\int_0^1 P_r\{T_k(u) \leq \rho_{0.95}(k)\} du = .95$ where $T_k(u)$ is a random variable that follows the noncentral t -distribution with $k-1$ degrees of freedom and the noncentrality parameter of $\sqrt{k}\Phi^{-1}(1-u)$, and Φ is the standard normal distribution function.

Multiple Components

The statistical methods for the determination of a single shelf-life of drug products with a single active ingredient are well established. However, many drug products contain more than one active ingredient in practice. The examples include Levite® (oral contraceptive drug), which contains two active ingredients, levonorgestrel and ethinylestradiol, and Premarin® (conjugated estrogens), which contains more than three active ingredients, including estrone, equilin, and 17 α -dihydroequilin. Furthermore, the multiple ingredients are often applied to herbal medicines in preclinical and clinical development.^[23] It is estimated

that as many as a quarter of all drugs come from natural sources, mostly plants.^[24] Also, it is common that one dose of traditional Chinese herbal medicine may contain multiple active ingredients, such as Menopause®, which contains black cohosh, wheat berries, Jujube fruit, licorice root, and kava. Those multiple active ingredients in this formula work together to improve the balance of progesterin and estrogen to relieve menopause symptoms.

Nevertheless, there is no discussion regarding the statistical methods for the determination of the shelf-life of drug products with multiple active ingredients in both the ICH and the FDA stability guidelines. For a drug product with multiple ingredients (components), the usual practice for the estimation of the expiration dating period is to consider the drug product as a whole rather than as individual components in terms of the percentages of the label claim of the drug product. It is also recognized that the degradations of individual components may vary from component to component. To account for the practical issues that may be encountered in the estimation of the drug shelf-life of drug products with multiple components, the naive approach is to use the minimum of expiration dating periods obtained from individual components being considered as the labeled expiration dating. As discussed before, the minimum approach either is too conservative, which may lose the clinical interest in practice, or lacks statistical justification. In a similar manner, Chow and Shao^[25] proposed using simultaneous lower confidence bounds for estimation of drug products with multiple components. This method is also conservative. As an alternative, they also suggested using principal components in conjunction with factor analysis to identify the most active components and then performing stability analysis using multivariate analysis to account for the relationships among components. However, the relative merit and disadvantages need further investigation.

Additionally, Pong and Raghavarao^[26] proposed a statistical method for estimating the shelf-life of drug products with two active ingredients. The idea of the proposed method is to derive a shelf-life estimator that is the linear combination of individual shelf-life from two components. The optimal weights for each component are chosen based on the minimum mean squared error of the true shelf-life, which is sensitive to the variability and degradation rates from individual components. In this method, the minimum approach is a special case of the class of estimators under consideration. This method had been further extended for drug product with n (> 2) ingredients.^[27]

CONCLUSION

Stability studies are essential in pharmaceutical research and development, because they provide a certain assurance that the drug products will meet the standards of identity, strength, quality, and purity of drug characteristics before

the drug expiration date. However, there is no or little discussion regarding the determination of the drug shelf-life of drug products with multiple components in the FDA and ICH stability guidelines. Therefore, it would be of future interest to investigate the shelf-life of drug products with multiple components in the field of stability analysis.

Exploratory Factor Analysis

Joseph C. Cappelleri and Robert A. Gerber

Pfizer Inc., New London, Connecticut, U.S.A.

Abstract

In exploratory factor analysis, there is initial uncertainty as to the number of factors being measured, and the results of the analysis are used to help solve for the number of factors. This entry introduces basic concepts of the common factor model and highlights a few major steps in conducting an exploratory factor analysis.

INTRODUCTION

Factor analysis is a multivariate method concerned with detecting and analyzing patterns based on the correlations among quantitative variables. In factor analysis, a set of measured variables is reduced into a smaller, more manageable set of unobservable factors that underlie the measured variables. The objective is to identify the number and the nature of the factors that are responsible for covariation in the data. For example, the Hospital Anxiety and Depression Scale (HADS) is a widely used questionnaire with 14 variables (or items), each measured on a four-point ordinal scale.^[1] A factor analysis revealed that, although the questionnaire contained 14 items, it was really just measuring two underlying factors (or constructs): anxiety and depression.^[2,3] Seven of the 14 questions measured anxiety, whereas the other seven measured depression.

Exploratory and confirmatory factor analyses are two major approaches to factor analysis. In exploratory factor analysis, there is initial uncertainty as to the number of factors being measured, and the results of the analysis are used to help solve for the number of factors. Exploratory factor analysis is suitable for generating hypotheses about the structure of the data. It can be used to lend structure and validity to the data. In addition, exploratory factor analysis can further refine an instrument by revealing what items may be dropped from the questionnaire because they contribute little to the presumed underlying factors.

Although exploratory factor analysis explores the patterns in the correlations of items (or variables), confirmatory factor analysis tests whether the correlations conform to the anticipated or expected scale structure. In confirmatory factor analysis, there must be not only a pre-specified number of unobserved factors (latent variables) being assessed, but also a theoretical framework of which observable (manifest) variables are related and not related to which factors. A more important distinction is that confirmatory factor analysis, unlike exploratory factor analysis, tests for a specified relationship between latent

factors and, in doing so, allows for testing hypotheses on what factors have effects on other factors.

In this entry, attention is restricted to exploratory factor analysis. Section “Basic Concepts” introduces basic concepts of the common factor model. Section “Comparison With Principal Component Analysis” compares exploratory factor analysis with principal component analysis, a related variable reduction technique. Section “Steps in Conducting an Exploratory Factor Analysis” highlights and illustrates a few major steps in conducting an exploratory factor analysis. Section “Further Reading” provides sources for further reading.

BASIC CONCEPTS

Common and Unique Factors

The matrix of correlations between observed variables (items) provides the basic building block for factor analysis. Consider a questionnaire with six items, each rated on a seven-point ordinal scale. The pattern of correlations between items may indicate, for example, that the first three questions happen to be strongly correlated with one another but essentially uncorrelated with the last three questions. Similarly, the last three questions may be strongly correlated with one another but essentially uncorrelated with the first three questions.

This grouping suggests two sets of variables. The three questions in each set are correlated with one another because they are all influenced by the same underlying factor. A factor, a hypothetical construct, is an unobservable (latent) variable that is believed to influence certain observable (manifest) variables that can be measured directly. A common factor is a factor that influences more than one observable variable and is “common” in the sense that more than one variable has it in common. In the current scenario, the first three observable variables are correlated because they have a factor in common; the

last three observable variables are correlated because they share a distinct, common factor.

The two common factors are not the only factors that influence the observed variables. A second type of factor—a unique factor—influences only one observed variable. A unique factor represents all of the independent factors, including the error component specific to a given variable, that are unique to that single variable. Each variable has its own unique factor.

Orthogonal versus Oblique Rotation

An orthogonal rotation is one in which the (common) factors are treated as uncorrelated and hence orthogonal. An oblique rotation, on the other hand, is one in which the factors are taken as correlated or associated. No implication is made, though, that one factor is expected to have a causal effect on the other.

Factor Loadings

Factor loadings are coefficients that indicate the importance of a variable to each factor. These coefficients are important because they signify the nature of the variables that most strongly relate to a factor; the nature of the variables helps to capture the nature and meaning of a factor.

Factor loadings appear in either a pattern matrix or a structure matrix. Factor loadings in a pattern matrix are essentially standardized regression coefficients. In this case the factors and observed variables are standardized to have unit variances, where the observable variables are dependent variables and the factors are explanatory variables. Pattern loadings may be therefore thought as optimal linear weights in predicting the variables from the factors. The factor pattern reflects the unique contribution that each factor makes to the variance of each variable.

Factor loadings in a structural matrix, on the other hand, represent the product-moment correlation between an observed variable and an underlying factor. Factor loadings, therefore, appear as standardized regression weights from the pattern matrix and correlation coefficients from the structural matrix. For an orthogonal factor analysis, but not for an oblique factor analysis, factor loadings from pattern and structural matrices are equivalent.

Model

In a factor analytic model, each observed variable can be viewed as a linear combination of the underlying factors, both common and unique. Suppose there are six observed variables and two retained common factors in a factor model. Each of the six observed variables can be viewed as a weighted sum of the two underlying factors, plus a variable-specific unique factor. For example, let Y_i be a subject's score on the first observed variable, F_1 and F_2 be

a subject's score on the two common factors, and U_i be the unique factor associated with Y_i . Algebraically,

$$Y_i = b_1(F_1) + b_2(F_2) + d_i(U_i)$$

where b_1 and b_2 represent the regression coefficients (weights) for the underlying common factors F_1 and F_2 , respectively, and d_i represents the regression weight for the unique factor associated with Y_i . A subject's score on Y_i is therefore determined by multiplying her scores on the underlying factors by the appropriate regression weights and then summing the results. The regression weights of the common factors are standardized and come from the factor pattern matrix. Generally, a different set of factor weights, and thus a different equation, is expected for each observed variable. A set of q common factors will have q corresponding regression weights ($b_1, b_2, \dots, b_{q-1}, b_q$).

An estimated factor score is an estimate of a subject's standing on a particular factor. Factor scores are estimated by creating linear composites of the observed variables, that is, by adding and optimally weighting each subject's scores on the observed variables. A score can be assigned to a subject on a given factor to indicate where he stands on each factor. If a factor analysis of 14 items suggests two factors, for instance, a subject will have an estimated factor score on one factor and another estimated factor score on the second factor. These two factor scores (instead of the larger set of 14 items) could then be used as predictor variables or dependent variables in subsequent analyses. Alternatively, instead of an estimated factor score, a factor-based scale score for an individual can be created by simply taking, say, an unweighted average of an individual's responses to the observed items belonging to a particular scale.

Communality and Unique Components

A communality is pegged to a given observed variable and refers to the variance in an observed variable that is accounted for by the set of common factors. Suppose a set of two common factors is retained. A communality of 0.8 for a variable, say the first variable, means that 80% of the variance for that variable is accounted by the two common factors. A high communality for a variable means the variable is strongly influenced by at least one of the factors. The communality is computed by squaring that variable's regression weights, or its factor pattern loadings, of all the retained common factors and then summing these squares.

In contrast to the communality, the unique component refers to the proportion of variance in a given observed variable that is not accounted for by the common factors. Once a communality of a variable is computed, it is easy to calculate the unique component: simply subtract the communality from one. If the communality of the first variable (Y_1) is 0.8, then 20% of the variance in Y_1 is accounted for by its unique factor, U_1 . The square root of the unique

component (i.e., the square root of 0.20), which is 0.45, becomes the weight given to U_1 (i.e., $d_1 = 0.45$).

COMPARISON WITH PRINCIPAL COMPONENT ANALYSIS

Exploratory factor analysis and principal components analysis are similar in some ways and, as a result, they are often mistaken for one another. Both exploratory factor analysis and principal component analysis are variable reduction procedures, reducing a number of variables to a smaller number. But the two procedures are generally different and not conceptually identical.

In factor analysis the observed variables are linear combinations of the underlying factors. In principal components analysis the principal components are linear combinations of the observed variables.

Factor analysis is better suited than principal component analysis to identify the number and nature of the latent factors that are responsible for covariation in the data set. In factor analysis, factors are extracted to account only for the common variance (variance accounted for by the common factors), while the unique variance remains unanalyzed. This extraction is accomplished by analyzing an adjusted correlation matrix with correlations between the observed variables off the diagonal of the matrix and communality estimates on the diagonal.

In principal component analysis, on the other hand, components are extracted to account for the total variance in the data set, both common and unique, and not just the common variance. This extraction is accomplished by analyzing an unadjusted correlation matrix with a correlation matrix having ones on the diagonal. Because principal component analysis makes no attempt to separate the common component from the unique component of each variable's variance, and factor analysis does, factor analysis is more appropriate than principal component analysis in identifying the factor structure of the data.

STEPS IN CONDUCTING AN EXPLORATORY FACTOR ANALYSIS

Factor analysis is typically conducted in a sequence of steps. A sequence of major steps is illustrated with the Patient Satisfaction with Insulin Therapy (PSIT) Questionnaire (Table 1). The PSIT is based on 15 items with each item based on a five-point Likert scale ranging from strongly agree to strongly disagree. Responses to each item on the questionnaire were analyzed so that a higher item score indicated a favorable attitude.

The questionnaire was self-administered at baseline and 12-week follow-up to subjects with type 1 diabetes recruited into a 12-week parallel study of an inhaled insulin

Table 1 The Patient Satisfaction with Insulin Therapy Questionnaire: Baseline Descriptive Statistics in a Trial ($n = 69$)^a

Items ^b	Standard	
	Mean	Deviation
1. I find it easy to take insulin the way I take it now.	3.58	1.28
2. I have no discomfort taking insulin the way I take it now.	3.07	1.38
3. I find it convenient to take insulin the way I take it now.	3.09	1.36
4. I am self-conscious about taking insulin away from home.	3.20	1.37
5. I find it easy to take all the doses of insulin my doctor recommends.	3.90	1.18
6. I find the time it takes for each dosing acceptable.	3.87	1.21
7. I find that my eating schedule can be flexible with few problems.	3.28	1.38
8. I prefer to stay home rather than take insulin away from home.	3.71	1.45
9. I do not mind measuring my blood glucose before each meal.	3.74	1.23
10. I feel good on my current insulin treatment schedule.	3.72	1.04
11. I find it difficult to take every dose of insulin my doctor recommends.	3.90	1.19
12. I find it difficult to take insulin away from home.	3.71	1.41
13. I would find it difficult to take insulin four times a day.	2.86	1.41
14. I find it easy to travel for a few days and take all my doses of insulin.	3.74	1.18
15. Overall, I am satisfied with my current way of taking insulin.	3.40	1.21

^aA higher item score (range 1–5) indicated a more favorable attitude. Hence, items 1, 2, 3, 5, 6, 7, 9, 10, 14, and 15 were reversed scored and analyzed so that 1 = strongly disagree, 2 = slightly disagree, 3 = neither agree nor disagree, 4 = slightly agree, 5 = strongly agree. Items 4, 8, 11, 12, and 13 were analyzed so that 1 = strongly agree, 2 = slightly agree, 3 = neither agree nor disagree, 4 = slightly disagree, 5 = strongly disagree.

regimen versus a conventional subcutaneously injected insulin regimen.^[4] In this entry, three major steps are illustrated for the factor analysis of the baseline responses of 69 subjects (Table 1).^[5] These steps are intended to help guide the conduct of an exploratory factor analysis.

Step 1: Determine the Number of Retained Factors

Three recommendations are offered in determining the number of factors to retain. One recommendation

is to use the scree test.^[6] The scree test is a rule-of-thumb criterion and involves the plot of the eigenvalue (i.e., the amount of variance that is accounted for by a given factor) associated with each factor (Fig. 1). The objective of a scree plot is to look for a break between factors with relatively large eigenvalues and those with smaller eigenvalues. Factors that appear before the break are taken to be meaningful and retained for rotation.^[6] For the data on the PSIT questionnaire, the scree plot (Fig. 1) depicted an abrupt break or discontinuity before factor 3, suggesting that only the first two factors were meaningful to be retained. A straight line can be drawn from factor 3 to factor 15 but not from factor 2 or factor 1 to factor 15.

A second recommendation in deciding on the number of factors involves retaining a factor if it accounts for a certain percentage of the variance in the data set. Although no fixed percentage is standard, we prespecified and required that at least 10% of the variance be explained by a retained factor in the PSIT data. The first factor accounted for 66% of the variance, and the second factor accounted for an additional 20%. The third factor accounted only for an additional 7% of the variance, and subsequent factors independently accounted for progressively lower percentages of variance.

The final recommendation when solving for the number of factors embraces criteria for interpretability: interpreting the substantive meaning of the retained factors and verifying that the interpretation makes sense about the subject matter. Four criteria for interpretability are given in Step 3: Interpret the Factors (below) and concurred with a two-factor solution for the example data.

Therefore, a two-factor solution was chosen based on the scree test, the percentage of variance explained by each factor, and interpretability criteria.

Step 2: Rotate the Chosen Factors

In common factor analysis, the observed items are viewed as linear combinations of the factors, and the elements of the rotated factor pattern are regression coefficients (or regression weights) associated with each factor in the prediction of an item score. When all of the items and factors are standardized to have a mean of 0 and standard deviation of 1, the regression weights become standardized regression coefficients. Relative to the initial and unrotated solution, which tends to be ambiguous, rotating (transforming) factors fosters a simpler structure of the data that leads to a more interpretable pattern.

For the PSIT data, the rotated factor matrix of pattern loadings with a promax rotation of two factors was used (Table 2). A promax rotation allows the retained factors to be oblique (correlated). The pattern loadings are essentially standardized regression coefficients comparable with those obtained in multiple regression. Their absolute values reflect the unique contribution that each factor makes to the variance of the observed item. The rotated factor pattern matrix was used to determine which groups of variables are measuring a given factor and to determine the meaning of each factor.

Step 3: Interpret the Factors

Four criteria were applied to judge interpretability and overall results, including the number of factors retained. First, at least three items should load on each retained factor. Second, the items that loaded on a given factor should share a common conceptual meaning. Third, the items that loaded on different factors should measure different conceptual meanings. Finally, the rotated factor pattern should demonstrate simple structure in that (i) most of the items should have high pattern loadings (say, $\geq |0.40|$) on one

Fig. 1 Scree plot showing the amount of variance accounted for by each factor. Note: Because the cumulative percentage of variance exceeds 100% at some points in the analysis, it was necessary mathematically that some trivial factors have negative eigenvalues

Table 2 Rotated Factor Pattern: Standardized Regression Coefficients^a

Items ^b	Factor 1	Factor 2
1. I find it easy to take insulin the way I take it now.	82 ^c	9
2. I have no discomfort taking insulin the way I take it now.	83 ^c	-15
3. I find it convenient to take insulin the way I take it now.	87 ^c	-20
4. I am self-conscious about taking insulin away from home.	3	61 ^d
5. I find it easy to take all the doses of insulin my doctor recommends.	47 ^c	34
6. I find the time it takes for each dosing acceptable.	57 ^c	25
7. I find that my eating schedule can be flexible with few problems.	55 ^c	16
8. I prefer to stay home rather than take insulin away from home.	-19	84 ^d
9. I do not mind measuring my blood glucose before each meal.	37 ^c	-7
10. I feel good on my current insulin treatment schedule.	58 ^c	-4
11. I find it difficult to take every dose of insulin my doctor recommends.	-1	70 ^d
12. I find it difficult to take insulin away from home.	9	82 ^d
13. I would find it difficult to take insulin four times a day.	5	50 ^d
14. I find it easy to travel for a few days and take all my doses of insulin.	60 ^c	21
15. Overall, I am satisfied with my current way of taking insulin.	80 ^c	10

factor and low loadings on the other factor and (ii) each factor should have high loadings for some items and low loadings for the others. All four criteria were met in this factor analysis with two factors (Table 2).

Factor 1 made a large and unique contribution to the variance of the following 10 items: easy to take, comfort, convenient, all doses, time, flexible, before meals, feel good, easy to travel, and satisfied—items 1, 2, 3, 5, 6, 7, 9, 10, 14, and 15 in Table 2. Because these items relate to convenience and ease of use of insulin therapy, Factor 1 was labeled “convenience/ease of use.” Factor 2 made a unique and noticeable contribution to the variance of the following five items: self-conscious, stay at home, difficult to take dose, away from home, and insulin intake four times—items 4, 8, 11, 12, and 13 in Table 2. Because these items relate to social stigma and use of insulin delivery away from home, factor 2 was labeled “social comfort.” The inter-factor correlation of 0.43 revealed a moderate positive correlation between the two factors. Higher levels of convenience and ease of use were associated with higher levels of social comfort. Fig. 2 summarizes and depicts the results of the factor analysis.

Further support for a two-factor solution and its interpretation came from the simple structure of the semipartial correlations from the reference structure matrix and the simple bivariate correlations from the factor structure matrix (data not shown). A semi-partial correlation represents a correlation between a variable and a common factor, after removing the effects of other common factors. A simple bivariate correlation represents a correlation between an item and a common factor. The three-factor solution, on the other hand, gave a vague interpretation on how certain items related to particular factors. In addition, its semipartial correlations were more ambiguous and less compelling in demonstrating simple structure compared with the semipartial correlations from the two-factor solution.

FURTHER READING

Detailed descriptions of exploratory factor analysis, as well as related techniques, abound elsewhere.^[2,3,7–14] In particular, Gorsuch^[10] has been a leading text that covers factor analysis in depth while avoiding detailed mathematics. Ki and Chow^[12] considered factor analysis in conjunction with principal component analysis for identifying factors in a quality-of-life questionnaire. Confirmatory factor analysis, not covered in this entry, is a special case of a broad class of models called structural equation models. Many sources are available on confirmatory factor analysis and structural equation models.^[11,15–24] In particular, Bollen^[15] has been a leading text on structural equations with latent variables. Exploratory factor analysis and confirmatory factor analysis on different data sets have appeared within the same article.^[25–27] Standard statistical software [e.g., SAS^[11]] is available for exploratory and confirmatory factor analyses. Specialized software for structural equation models include AMOS,^[28] EQS,^[29] LISREL,^[30] and MPLUS.^[31]

CONCLUSIONS

Exploratory factor analysis is a multivariate, data-reduction method that identifies the number and the nature of the factors that are responsible for covariation in the data. The objective is to arrive at a manageable and meaningful set of unobservable factors that underlie the measured variables. In exploratory factor analysis, there is initial uncertainty as to the number of factors being measured. The results of exploratory factor analysis are used to help solve for the number of factors, generating hypotheses about the structure of the data. Exploratory factor analysis can be used to lend structure and validity to the data. In addition, it can further refine an instrument by revealing what items may be dropped from the questionnaire because they contribute little to the presumed underlying factors.

One recommendation on how many factors to retain is to use a scree test. In addition, other criteria can be used to evaluate the number of factors and their content for suitability. Among these criteria are items that load on a given factor should have a shared conceptual meaning and items that have high standardized pattern loadings (≥ 0.40 in absolute value) on one factor should also have low loadings on the other factors.

This entry introduced the basic concepts of the common factor model. Exploratory factor analysis was compared and contrasted with principal component analysis, a related variable reduction technique. Major steps of exploratory factor analysis were illustrated with an example on patient satisfaction for individuals with diabetes. Sources for further reading were provided.

Abstract

Presented in this entry is a description of the phenomenon known as extra variation or overdispersion, along with a review of the literature. Several testing models are detailed in an effort to give examples of this phenomenon.

INTRODUCTION

Consider a study where experimental units are clusters and each elemental unit within the cluster is classified into two mutually exclusive categories. If we assume elemental units are independent, the binomial model is appropriate for analyzing the data. But clustering introduces a lack of independence, and as a consequence the data usually exhibit larger variances than the variance permitted by the binomial model. This phenomenon is known as *extra variation* or *overdispersion*; in practice, seems to be the norm and not the exception.^[1] Extra variation is also observed for count data analyzed under the Poisson model when the residual variation obtained after a Poisson model may be greater than that can be attributed to the sampling variation assumed by the model. The phenomenon of *under dispersion* is less common, but it can be induced, for example, by stratified sampling. Under dispersion can also occur when there is competition for a positive response. As discussed in Stigler,^[2] examples of extra variation arising from a clustered population, can be traced in the literature as far back as the year 1876. Early remarks related with extra variation under the Poisson model are found in Student.^[3]

Examples of binomial (multinomial) models with extra variation may arise in the following: (i) teratological study of a genetic trait that is passed on with a certain probability to offspring of the same mother; (ii) reproductive toxicity experiments in which chemicals are administered to litters and responses are measured on individual fetuses; (iii) experiments in which individuals receiving treatments are allowed to interact with each other via support groups, as in stop-smoking programs or stop-drinking programs; (iv) household surveys in which respondents within a household (or a neighborhood) may be strongly influenced by one or two individuals; (v) in studies in which summary measures are reported after repeated application of a treatment or repeated use of a product. The phenomenon

of extra variation is widely recognized by researchers and practitioners alike. A large number of papers in the literature discuss examples, with real data illustrating the extra variation phenomenon and its consequences on erroneous inferences due to inflated type I error rates. Some relevant examples in the areas of teratology and toxicology are Williams,^[4–6] Kupper and Haseman,^[7] Haseman and Kupper,^[8] Kupper et al.,^[9] Shirley and Hickling,^[10] Paul,^[11] Pack,^[12] Lefkopoulou et al.,^[13] Carr and Portier^[14] Donner et al.,^[15] Morel and Neerchal.^[16] Other important examples of extra variation are found in Rosner^[17] and Donner^[18] in ophthalmology; Altham^[19] and Cohen^[20] in studies of hospitalized sibling pairs; Crowder^[21] in the analysis of seed germination; Heckman and Willis^[22] in connection with a panel study; Efron^[23] in the analysis of toxoplasmosis in 34 cities of El Salvador; Moore^[24] in the modeling of chromosome aberration in survivors of the atomic bomb of Hiroshima. This list of examples is by no means exhaustive. Real examples of overdispersion under the Poisson model are found in the analysis of number of tumors in rats, Gail et al.^[25] and Lawless,^[26] in a longitudinal clinical trial aimed to study the number of epileptic seizures, Breslow and Clayton,^[27] on the frequency of recurrence of bladder cancer, Dean and Balshaw.^[28] An assessment of efficacy of vitamin C in reducing child mortality in Indonesia is found in Zeger and Edelstein.^[29] In general, Poisson models with extra variation arise when any of the assumptions of the Poisson distribution is violated such as in the analysis of counts and rates of longitudinal studies.

OVERVIEW

The phenomenon of binomial outcomes with extra variation is usually characterized in terms of the first two moments. Suppose that T is a binomial random variable representing the number of successes out of m trials. Then,

$$E(T) = m\pi \quad (1)$$

where π represents the probability of success of each Bernoulli trial. Assume now that the Bernoulli trials $Y_1, Y_2, \dots, Y_m$ that encompass T are positively correlated, so the usual assumption of independence in the binomial model is violated. The case “positively correlated” corresponds to extra variation, which is the focus of this chapter. The occurrence of under dispersion is less common and corresponds to a negative correlation among the Bernoulli outcomes that comprise T . Thus, suppose that for two distinct Bernoulli outcomes the correlation is ρ^2 , $0 < \rho^2 < 1$. We use ρ^2 to indicate the correlation is non-negative. Then, it can be shown

$$\text{Var}(T) = m\pi(1 - \pi)\{1 + \rho^2(m - 1)\} \quad (2)$$

A random variable T with first two moments as in Eqs. (1) and (2) is said to have extra variation or overdispersion relative to the binomial model. When $\rho = 0$ Eq. (2) becomes the variance of a binomial distribution. Among sampling practitioners, the parameter ρ^2 represents the *intracluster correlation* and the factor $\{1 + \rho^2(m - 1)\}$ is known as *design effect*. The definition of extra variation can be extended to the case of multinomial distribution in a similar way. When Y is a Poisson-type of random variable, Y is said to have overdispersion if its first two moments are of the form

$$E(Y) = \mu, \quad \mu > 0 \quad (3)$$

and

$$\text{Var}(Y) = \mu + \kappa\mu^2 = \mu(1 + \kappa\mu), \kappa > 0 \quad (4)$$

The parameter κ is known as the dispersion parameter. Observe that when $\kappa = 0$, variance in Eq. (4) becomes that of the Poisson model. Dean^[30] provides an additional form of overdispersion by considering $\text{Var}(Y) = \mu(1 + \kappa)$.

There are several approaches for modeling data exhibiting extra variation. A widely used method is the one known as quasi-likelihood, where the binomial variance is inflated by a suitable constant. McCullagh and Nelder^[1] give details of the method. We discuss this method in “Quasi-likelihood Models.” Other methods include the use of likelihood models, as we will explain in “Likelihood Models.” We present a goodness-of-fit statistic to test the adequacy of likelihood models in “A Goodness-of-fit Test for Extra Variation Models.” The generalized estimating equations methodology proposed by Liang and Zeger^[31] and by Zeger and Liang,^[32] which is closely related to the quasi-likelihood method and generalized linear models, is reviewed in “Generalized Estimating Equations Models.” More recently, generalized models that include random effects to model the heterogeneity between individuals within a cluster have been proposed. Some references for

this method are McGilchrist,^[33] Drum and McCullagh,^[34] Breslow and Clayton,^[35] Karim and Zeger,^[36] Zeger and Karim,^[37] Goldstein,^[38] Schall,^[39] and Zeger et al.^[40] Random effect models are reviewed in “Random Effect Models.” We will present several examples related to preclinical and clinical experiments from biopharmaceutical studies throughout the remainder of this chapter.

QUASI-LIKELIHOOD MODELS

In 1974 Wedderburn^[41] proposed the use of quasi-likelihood models. A quasi-likelihood function is defined without the knowledge of the likelihood function, but through its relation between the mean and the variance of each observation for which the quasi-likelihood function is being constructed. The structure of the first derivative of the quasi-likelihood function (without knowing the function from which this derivative is obtained from) resembles the structure of the score function, that is, the derivative of the logarithm of the likelihood function. Parameter estimates are obtained by solving the score function, often iteratively by methods such as Gauss–Newton. In order to understand quasi-likelihood models it is necessary to have some familiarity with *generalized linear models* (GLM). A quick introduction to GLM can be presented via the popular logistic and Poisson regression models. Let Y_j , $j = 1, 2, \dots, n$, represent n independent random variables belonging to a distribution in the exponential family such that $E(Y_j) = \mu_j$. Because the Y_j 's belong to the exponential family, it is possible to prove

$$\text{Var}(Y_j) = \phi v(\mu_j),$$

where the multiplier ϕ is known as the *dispersion* (or *scale*) parameter. In the case of the normal distribution, the parameter ϕ corresponds to the variance σ^2 . For some members of the exponential family the dispersion parameter is not present in the sense that $\phi \equiv 1$, as in the case of the Binomial (Multinomial) and Poisson distributions. Overdispersion under these distributions arises when $\phi > 1$.

In GLM, the mean μ_j , $j = 1, 2, \dots, n$, depends on a k -dimensional row vector of known covariates x_j and a k -dimensional column vector of unknown parameters β , through a smooth function $g(\cdot)$ so that

$$g(\mu_j) = x_j \beta = \sum_{i=1}^k x_{ji} \beta_i \quad (5)$$

The function $g(\cdot)$ is known as the *link function* and $\eta_j = x_j \beta$ is known as the *linear predictor*. Note that the inverse of the link function yields $\mu_j = g^{-1}(x_j \beta)$, the mean function. Let y represent the vector of observations $y = (y_1, y_2, \dots, y_n)^t$, and let $L(\beta, \phi; y) = \sum_{j=1}^n \ln \{f(y_j; \beta, \phi)\}$ represent the

log-likelihood function. Here $f(y_j; \beta, \phi)$ represents the density (or probability function) of Y_j , $j = 1, 2, \dots, n$, and the Y_j 's belong to the exponential family. The k -dimensional column vector of first derivatives of the log-likelihood function with respect to β , is the *gradient* or *score vector* that is,

$$u(\beta) = \frac{\partial L(\beta, \phi; y)}{\partial \beta}$$

The $k \times k$ matrix of second derivatives is the *Hessian*, given by

$$H(\beta) = \frac{\partial^2 L(\beta, \phi; y)}{\partial \beta \partial \beta^t}$$

The *Fisher Information Matrix (FIM)* is negative of the expected value of the Hessian, that is

$$I = -E \left[\frac{\partial^2 L(\beta, \phi; y)}{\partial \beta \partial \beta^t} \right] = E \left[\frac{\partial L(\beta, \phi; y)}{\partial \beta} \frac{\partial L(\beta, \phi; y)}{\partial \beta^t} \right]$$

In GLM, in order to obtain $\hat{\beta}$, the *maximum likelihood estimator (MLE)* of β , one needs to solve the estimating equations

$$\frac{\partial L(\beta, \phi; y)}{\partial \beta} = 0 \quad (6)$$

Parameter estimates are obtained by solving Eq. (6), usually by iterative methods such as Newton–Raphson or Gauss–Newton procedure. Nelder and Wedderburn,^[41] and Wedderburn,^[42] showed that the solution of the maximum likelihood equations is equivalent to an iterative weighted least-squares procedure. If the current estimate of β is denoted by $\hat{\beta}_{(s)}$, the improved estimate $\hat{\beta}_{(s+1)}$ is

$$\hat{\beta}_{(s+1)} = \hat{\beta}_{(s)} + (\hat{D}_{(s)}^t \hat{V}_{(s)}^{-1} \hat{D}_{(s)})^{-1} \hat{D}_{(s)}^t \hat{V}_{(s)}^{-1} (y - \hat{\mu}_{(s)}) \quad (7)$$

where $\hat{\mu}_{(s)}$, $\hat{V}_{(s)}$ and $\hat{D}_{(s)}$ correspondent respectively to the n -dimensional column vector of means $\mu = (\mu_1, \mu_2, \dots, \mu_n)^t$, the $n \times n$ diagonal matrix of variance functions $V = \text{Diag}\{v(\mu_1), v(\mu_2), \dots, v(\mu_n)\}$ and the $n \times k$ matrix of first derivatives

$$D = \left(\frac{\partial \mu_1}{\partial \beta}, \frac{\partial \mu_2}{\partial \beta}, \dots, \frac{\partial \mu_n}{\partial \beta} \right)^t, \text{ all terms evaluated at } \beta = \hat{\beta}_{(s)}.$$

If the canonical link is assumed (logit link for the binomial distribution and logarithm link for the Poisson), it can be shown that iterative procedure in Eq. (7) further reduces to

$$\hat{\beta}_{(s+1)} = \hat{\beta}_{(s)} + (X^t \hat{V}_{(s)} X)^{-1} X^t (y - \hat{\mu}_{(s)}) \quad (8)$$

As in GLMs, in quasi-likelihood models the mean μ_j depends on a k -dimensional row vector of known covariates x_j and a k -dimensional column vector of unknown parameters β , through a smooth function $g(\cdot)$ as in Eq. (5). As pointed out earlier, in quasi-likelihood models, the structure of the first derivative of the quasi-likelihood function (without knowing the function from which this derivative is obtained from) resembles the structure of the *score function*, i.e., the derivative of the logarithm of the likelihood function. For the one-parameter exponential family, the log likelihood is the same as the quasi-likelihood. For a single observation, the quasi-likelihood function is defined as

$$\frac{\partial Q(Y_j, \mu_j)}{\partial \mu_j} = \frac{Y_j - \mu_j}{\phi v(\mu_j)} \quad (9)$$

Note that in Eq. (9), the function $Q(y, \mu)$ is such that its first derivative resembles the log-likelihood function of distributions in the exponential family, $Q(y, \mu) = \int_{-\infty}^{\mu} \frac{y-t}{\phi v(t)} dt + C$. The quantity

$$Q(y, \mu) = \sum_{j=1}^n Q(y_j, \mu_j) \quad (10)$$

is known as the *quasi-likelihood* (or more precisely as the *log-quasi-likelihood*) based on the data $y = (y_1, y_2, \dots, y_n)^t$ and the mean vector $\mu = (\mu_1, \mu_2, \dots, \mu_n)^t$. The quasi-likelihood estimate of β , say $\hat{\beta}$, is obtained by solving Eq. (10) with respect to β , that is

$$U(\beta) = \frac{\partial Q(y, \mu)}{\partial \beta} = 0 \quad (11)$$

These equations can be written as

$$\sum_{j=1}^n \frac{y_j - \mu_j}{\phi v(\mu_j)} \frac{\partial \mu_j}{\partial \beta} = 0 \quad (12)$$

whose solution in β does not require knowledge of ϕ . Therefore, they can be solved using the iterative weighted least-squares procedure as in Eq. (7) or as in Eq. (8). Once the iterative procedure has converged, the estimated covariance matrix is inflated by a consistent estimator of ϕ . Two common estimators of ϕ are based on the *deviance* and on *Pearson's Chi-square*, each statistic divided by its degrees of freedom. Assuming t_j is a realization of $T_j \sim \text{Binomial}(\pi_j, m_j)$, and y_j a realization of $Y_j \sim \text{Poisson}(\lambda_j)$, T_j 's and Y_j 's independent, $j = 1, 2, \dots, n$, the deviance and Pearson's chi-square for the binomial distribution are

$$D = 2 \sum_{j=1}^n \left\{ t_j \log \left(\frac{t_j}{m_j \hat{\pi}_j} \right) + (m_j - t_j) \log \left(\frac{m_j - t_j}{m_j - m_j \hat{\pi}_j} \right) \right\} \quad (13)$$

$$X^2 = \sum_{j=1}^n \frac{(t_j - m_j \hat{\pi}_j)^2}{m_j \hat{\pi}_j (1 - \hat{\pi}_j)} \quad (14)$$

Similarly, for the Poisson distribution we have

$$D = 2 \sum_{j=1}^n \left\{ y_j \log \left(\frac{y_j}{\hat{\lambda}_j} \right) - (y_j - \hat{\lambda}_j) \right\} \quad (15)$$

$$X^2 = \sum_{j=1}^n \frac{(y_j - \hat{\lambda}_j)^2}{\hat{\lambda}_j} \quad (16)$$

We now see some examples.

We first consider the simple case where $T_1, T_2, \dots, T_n$ are random variables with extra variation relative to the binomial model so that the mean and the variance of each random variable are as in Eqs. (1) and (2). Using the notation for quasi-likelihood models, we have $\mu_j = mp$, $v(\mu_j) = mp(1-p)$, and $\phi = \{1 + \rho^2(m-1)\}$ for each j , $j = 1, 2, \dots, n$. Here, the link function is the identity. Also, there are not covariates associated with the responses. To illustrate the estimation procedure, consider the data in Table 1, taken from a clinical trial. The study consisted of $n = 17$ subjects who brushed their teeth for six consecutive weeks with an experimental dental paste. The pH was measured at the end of the study at four sites of each subject's mouth ($m = 4$). It is believed that if the $\text{pH} \leq 6.5$, the subject is at higher risk of oral disease. For each site of each subject, we created a binary outcome variable, taking the value of "1" if the $\text{pH} \leq 6.5$ and "0" otherwise. Table 1 provides the distribution of the T_j 's (total number of mouth sites with $\text{pH} \leq 6.5$). The quasi-likelihood estimate of π is

$$\hat{\pi} = \frac{\sum_{j=1}^n T_j}{nm} \quad (17)$$

The estimated variance under the assumption that T_j 's are truly Binomial random variables, the so called naïve variance estimate, would be

$$\hat{V}(\hat{\pi}) = \frac{\hat{\pi}(1-\hat{\pi})}{nm} \quad (18)$$

The Pearson's chi-square statistic in Eq. (14) divided by its degrees of freedom ($n-1$) is a consistent estimator of ϕ . In this example

Table 1 pH Data

Number of mouth sites with $\text{pH} \leq 6.5$	0	1	2	3	4
Number of subjects	4	4	6	2	1

$$\hat{\phi} = \frac{\sum_{j=1}^n (t_j - m\hat{\pi})^2}{m\hat{\pi}(1-\hat{\pi})(n-1)} \quad (19)$$

The quasi-likelihood estimated variance of $\hat{\pi}$ is the naïve variance in Eq. (18) times the estimate of the scale parameter in Eq. (19). Thus, the quasi likelihood results are: $\hat{\pi} = 0.3824$, $\hat{\phi} = 1.4712$ and $se(\hat{\pi}) = 0.0715$. An approximated 95% confidence interval for π is given by (0.24, 0.52). Because the disease rate (proportion of sites with $\text{pH} \leq 6.5$) was approximately 71% at baseline, it is believed that the experimental toothpaste was efficacious in reducing the proportion of mouth sites at higher risk of oral disease.

For a discussion on quasi-likelihoods models we refer the reader to Cox and Snell.^[44] The use of quasi-likelihood models becomes more complex in the situation we are going to consider next.

Suppose that $T_1, T_2, \dots, T_n$ are independent random variables with extra variation relative to the binomial model such that $E(T_j) = m_j \pi_j$, $\text{Var}(T_j) = m_j \pi_j (1 - \pi_j) \{1 + \rho^2(m_j - 1)\}$, and $\ln(\pi_j / (1 - \pi_j)) = \mathbf{x}_j \boldsymbol{\beta}^0$. In order to estimate $\boldsymbol{\beta}$ and ρ simultaneously, Williams^[5] modified the iterative weighted least-squares procedure in Eq. (8) to allow the weights (inflation factors) $w_j^{-1} = \{1 + (m_j - 1)\rho^2\}$ to be used in conjunction with the variance function $v_j = m_j \pi_j (1 - \pi_j)$. In Williams's paper the intra-cluster correlation is denoted by ϕ . Note that the variance of T_j is $v_j w_j^{-1}$. For known ρ^2 , the quasi-likelihood estimator of $\boldsymbol{\beta}$ can be solved iteratively as

$$\hat{\boldsymbol{\beta}}_{(s+1)} = \hat{\boldsymbol{\beta}}_{(s)} + (\mathbf{X}' \mathbf{W} \mathbf{V} \mathbf{X})^{-1} \mathbf{X}' \mathbf{W} (\mathbf{y} - \boldsymbol{\mu}) \quad (20)$$

where $\mathbf{V} = \text{Diag}\{m_1 \pi_1 (1 - \pi_1), m_2 \pi_2 (1 - \pi_2), \dots, m_n \pi_n (1 - \pi_n)\} \equiv \text{Diag}(v_1, v_2, \dots, v_n)$ and

$$\mathbf{W} = \text{Diag}\left\{\frac{1}{1 + (m_1 - 1)\rho^2}, \frac{1}{1 + (m_2 - 1)\rho^2}, \dots, \frac{1}{1 + (m_n - 1)\rho^2}\right\} \equiv \text{Diag}(w_1, w_2, \dots, w_n).$$

Williams performed Taylor's series expansion on $E(X^2)$ in order to derive the moment estimator ρ^2 with X^2 defined as in Eq. (14). At each step of the iterative procedure the updated $\hat{\boldsymbol{\beta}}$ is used to obtain an updated $\hat{\rho}^2$. The latter is used to improve $\hat{\boldsymbol{\beta}}$ in the next iteration. We refer the reader to Williams^[5] for more details.

To illustrate the single variance inflation procedure and Williams^[5] approach, consider the ossification data of Table 2, which has been previously analyzed by Morel and Neerchal.^[16] The data come from a two-way factorial design with 81 pregnant C57BL/6J mice. The purpose of the experiment was to investigate the synergistic effect of phenytoin and trichloropropene oxide. The presence or absence of ossification at the phalanges is considered a measure of the teratogenic effect of the substances under study. At some

phalanges the ossification did not occur at all; in some others the ossification was almost complete. The middle third phalanges were selected because they provided about 50% chance of ossification in the control groups. For illustration purposes, we only analyzed the response of the left middle third phalanx. In the experiment each pregnant mouse was randomly allocated to an untreated control group (Control), a sham control group (Sham) receiving gavages of water, and three treated groups receiving daily, by gastric gavages, 60 mg/kg of phenytoin (PHT), 100 mg/kg of trichloropropene oxide (TCPO), and 60 mg/kg phenytoin and 100 mg/kg of trichloropropene oxide (PHT + TCPO). For illustrative purposes, the two controls were combined and will refer to as combined controls. The experiment thus can be seen as a 2×2 factorial, with TCPO and PHT as the two factors. The levels of TCPO are 0 mg/kg and 100 mg/kg, and the levels of PHT are 0 mg/kg and 60 mg/kg. The data on the left middle third phalanx are shown in Table 2.

Table 3 depicts the beta estimates and their standard errors after fitting the full factorial logistic regression model under no extra variation (fetuses within the litters are wrongly assumed to be independent) and under the two extra variation quasi-likelihood models previously discussed. The single variance inflation approach is based

on multiplying the “naïve” covariance matrix of the beta estimates by a consistent estimator of the scale parameter. In this example we picked the deviance in Eq. (13) divided by its degrees of freedom. The no-extra variation model and the single-inflation-factor quasi-likelihood model differ in that the variance-covariance matrix of the latter is 3.77 times the variance-covariance matrix of the former. The estimation procedure proposed by Williams^[5] produced results very consistent with those obtained under the single-inflation-factor quasi-likelihood model. Williams’s model differs from the “naïve” model in that Williams uses the weights $w_j = 1/\{1 + 0.410875(m_j - 1)\}$ which were obtained iteratively.

We now turn to extra variation Poisson models. Similar to extra variation binomial models, extra variation Poisson models are used to accommodate higher variability in the data than permitted by the usual Poisson model. One way to accomplish this is by letting the mean of the Poisson distribution vary according to a prior distribution, with possibly some unknown parameters. That is, we consider $m_1, m_2, \dots, m_n$ are random counts such that m_j for $j = 1, 2, \dots, n$ is distributed as a Poisson random variable with mean λ_j . Furthermore, assume that λ_j is a random variable with density function $f(\lambda)$ such that $E(\lambda_j) = \mu$ and $V(\lambda_j) = \psi\mu^2$. We are assuming $\psi > 0$; otherwise the distribution of the λ_j ’s would be degenerate at the value of μ . Then the unconditional mean and variance of m_j are $E(m_j) = \mu$ and $\text{Var}(m_j) = \mu(1 + \psi\mu)$, and the counts m_j ’s have extra variation relative to the Poisson model. When the prior distribution on the λ_j ’s is gamma, then the marginal distribution (unconditional distribution) of the m_j ’s is negative binomial (see Johnson et al.^[44]) The assumption of common mean μ can be relaxed and, as in the binomial case, the variance of the Poisson model can be inflated with a constant ϕ ($\phi > 1$) in order to account for extra variation. Thus we can have the counts m_j ’s such that $E(m_j) = \mu_j$ and $\text{Var}(m_j) = \phi\mu_j$, whereas before μ_j depends on a k -dimensional row vector of known covariates x_j and an k -dimensional column vector of unknown parameters β^0 , throughout a smooth function $g(\cdot)$, $g(\mu_j) = x_j\beta^0$. The natural choice for $g(\cdot)$ is

^aNumber of incident vertebral fractures, person-years of observation.

the logarithm function, which is the “canonical link” if the m_j 's were really distributed as Poisson ($\phi = 1$). Let us consider an example of Poisson counts with extra variation.

In a clinical study of osteoporotic patients at high risk of vertebral fractures, subjects were randomly assigned either to a group receiving active therapy (bisphosphonate) ($n = 28$) or to a placebo group ($n = 25$). The number of incident vertebral fractures (new and worsening) was measured during a period of time that lasted between approximately 14 and 39 months. The data are presented in Table 4.

Let m_{ij} and Y_{ij} represent the number of vertebral fractures and the years of observation of the j -th subject in the i -th treatment group. Conditioning on Y_{ij} , we fitted the extra variation Poisson model $E(m_{ij}) = \mu_{ij}$, $\text{Var}(m_{ij}) = \phi\mu_{ij}$, $\phi > 1$, and link function $\ln(\mu_{ij}/Y_{ij}) = \alpha + \tau_i$, where α is an overall mean and τ_i the effect of the i -th treatment group. The estimates are obtained by using iterated re-weighted least squares as previously described under the assumption that $\phi = 1$. Then, the variance-covariance matrix of the parameter estimates is inflated with a consistent estimate of ϕ . In this example we have chosen the Pearson's chi-square statistic in Eq. (16) divided by its degrees of freedom. The results of this estimation procedure for the vertebral fracture data are presented in Table 5. The estimated fractures-per-year rates are $e^{-0.0449} = 0.96$ for the placebo group and $e^{-0.0449-0.9000} = 0.39$ for the bisphosphonate group, indicating a highly significant (p -value = 0.0025) reduction in the number of vertebral fractures in the bisphosphonate group, compared to placebo. The estimate of the inflation factor (scale parameter) ϕ is 1.7311. Another common estimator of ϕ is the deviance in Eq. (15) divided

by its degrees of freedom, which in this example turned out to be 1.8472.

LIKELIHOOD MODELS

In this section we will discuss estimating extra variation models using proper likelihood functions. A likelihood with first two moments as in Eqs. (1) and (2) can be obtained as the marginal distribution of the total number of successes, where its conditional distribution is binomial and the probability of success varies from cluster to cluster according to a certain distribution. Let $T_1, T_2, \dots, T_n$, represent independent random variables such that given the j -th random variable, $j = 1, 2, \dots, n$, T_j is distributed binomial (P_j, m). Furthermore, assume that the P_j 's are themselves random variables distributed according to a distribution in the interval (0,1) with density function $f(P)$ (or probability function if the distribution of P is discrete) such that $E_f(P_j) = \pi$ and $V_f(P_j) = \rho^2\pi(1 - \pi)$. Then it can be shown that the unconditional mean and variance of each T_j are as in Eqs. (1) and (2). Under a prior $f(P)$, for any $t = 0, 1, 2, \dots, m$,

$$\Pr(T = t) = E_f\{\Pr(T = t)\} = \int_0^1 \binom{m}{t} P^t (1-P)^{m-t} f(P) dP \quad (21)$$

A distribution of the form in Eq. (21) is said to be a mixture, with the prior $f(P)$ being the mixing distribution. If $f(P)$ is continuous, the unconditional distribution of T is an infinite mixture. If the prior $f(P)$ is discrete and finite, the integral symbol in Eq. (21) changes to a finite summation, and the resulting distribution is a finite mixture. Two examples of mixture distributions used to model extra variation are the beta-binomial distribution originally used by Skellam^[45] and the finite-mixture distribution proposed by Morel and Nagaraj.^[46] We first consider the beta-binomial distribution.

Let $f(P)$ be the density function of a beta distribution with parameters $a = C\pi$ and $b = C(1 - \pi)$, where $C = (1 - \rho^2)/\rho^2$. Note that $E_f(P) = a/(a + b) = \pi$ and

Table 5 Estimates, Standard Errors, Chi Squares, and p -values for Poisson Extra Variation model of Vertebral Fracture Data

Parameter	Estimate	Standard Error	Wald Chi-square	p -value
Intercept	-0.0449	0.1632	0.08	0.7833
Bisphosphonate	-0.9000	0.2974	9.16	0.0025
Scale (ϕ)	1.7311			

$V_f(P) = ab/(a+b+1)(a+b)^2 = \rho^2\pi(1-\pi)$. Thus, as noted earlier, the unconditional distribution of T exhibits extra variation. It can be shown that, for any t , $t = 0, 1, 2, \dots, m$,

$$\Pr(T = t) = \binom{m}{t} \frac{\prod_{k=1}^t (C\pi + k - 1) \prod_{k=1}^{m-t} \{C(1-\pi) + k - 1\}}{\prod_{k=1}^m (C + k - 1)} \quad (22)$$

where $C = (1 - \rho^2)/\rho^2$ and a product from $k = 1$ to $k = 0$ is defined as 1. The probability function of Eq. (22) defines the beta-binomial distribution with parameters π , ρ , and m and denoted as beta-binomial $(\pi, \rho; m)$.

Morel and Nagaraj^[46] proposed a new distribution for modeling extra variation where the unconditional distribution of the total number of successes T can be obtained from placing on P a two-point prior distribution on the points $(1 - \rho)\pi + \rho$ and $(1 - \rho)\pi$ with probabilities π and $(1 - \pi)$, respectively. In this case, the unconditional probability function of T turns out to be, for $t = 0, 1, \dots, m$,

$$\Pr(T = t) = \pi \Pr(X_1 = t) + (1 - \pi) \Pr(X_2 = t) \quad (23)$$

where $X_1 \sim \text{binomial}((1 - \rho)\pi + \rho; m)$ and $X_2 \sim \text{binomial}((1 - \rho)\pi; m)$. Note that this is a mixture of two binomial distributions. If T has the distribution given by Eq. (23), it is denoted as $T \sim \text{finite-mixture}(\pi, \rho; m)$. The finite-mixture distribution results from an effort to model meaningfully the physical mechanism behind the extra variation. It can be derived in the following way.

Let $Y, Y_1^0, \dots, Y_m^0$ be independent and identically distributed Bernoulli (π) random variables. For each i , $i = 1, \dots, m$, define Y_i as Y with probability ρ , or as Y_i^0 with probability $(1 - \rho)$, $0 \leq \rho \leq 1$. Each Y_i can be represented as $Y_i = YI(U_i \leq \rho) + Y_i^0I(U_i > \rho)$, where the U_i 's are independent uniform $(0, 1)$ random variables, and $I(\cdot)$ denote an indicator function. In this model for clumped data, the response of any member of the cluster is the same as Y , with probability ρ . Also, for $i \neq j$ it can be shown that $\Pr(Y_i = 1 | Y_j = 1) = \rho^2$. That is, the conditional probability that a member of the cluster responds positively, given that one of the others in the cluster has already responded positively, is ρ^2 . If we let T be the sum of the Y_i 's, then $T = Y \sum_{i=1}^m I(U_i \leq \rho) + \sum_{i=1}^m Y_i^0 I(U_i > \rho)$. This leads to the following representation of T :

$$T = (Y'N) + (X | N) \quad (24)$$

where $N \sim \text{binomial}(\rho; m)$, $Y \sim \text{Bernoulli}(\pi)$, N and Y independent, and $(X | N) \sim \text{binomial}(\pi; m - N)$ if $N < m$. It can be shown [see Morel^[47]] that the probability function of T in Eq. (24) is given by Eq. (23). Under representation in Eq. (24), the outcome given by Y is duplicated a random number of times N , $N = 0, 1, \dots, m$. This is the number

of units in the cluster exhibiting the same behavior. The remaining $m - N$ units within the cluster provide independent Bernoulli responses. Contribution of these $m - N$ units to the total count T is represented by $(X | N)$. Fig. 1 illustrates the representation of a cluster of size $m = 7$. The cluster is thought of as having two subgroups. One is of size 4 (N ; in general $0 \leq N \leq 7$), and it consists of those elemental units that greatly influence each other and provide identical responses.

The three elemental units forming the second subgroup respond independently of each other and of the first subgroup. Their responses have been shown by a “?” to indicate that they may be either a “0” or a “1.” Clearly, the binomial count T in Eq. (24) exhibits extra variation, because the individual respondents (either by consulting each other before responding or by a natural biological inheritance) provide more similar responses than one would expect from independent Bernoulli trials. As far as the authors know, the finite-mixture is the only distribution that provides a clear interpretation of the underlying cluster mechanism. To illustrate the fitting of the beta-binomial and finite-mixture distribution, we now present an example on chromosome association.

Skellam^[45] analyzed data on the secondary association of chromosomes in *Brassica*, a group of Old World temperate zone herbs of the mustard family with beaked cylindrical pods (similar to cabbage). This is the first example in the literature where the beta-binomial distribution was formally used to model extra variation. At meiosis, the special process of cell division, there are three pairs of bivalents. A *bivalent* is a structure consisting of two paired homologous chromosomes. The paired chromosomes in each bivalent may or may not show association. For a nucleus i , $i = 1, 2, \dots, n$, let T_i represent the total number of pairs of bivalents showing association, T_i , $i = 0, 1, 2, 3$. If the probability of association is constant for all nuclei and the same for all pairs of bivalents, the binomial distribution would be appropriate for this problem. As we will see next, extra variation is present in this example, and both

Fig. 1 Two possible outcomes for a cluster of size $m = 7$ under the finite-mixture distribution. Some elemental units provide identical responses, either “1,” as in (a), or “0,” as in (b). The “?” symbol represents elemental units responding independently, with either a “0” or a “1”

Table 6 Chromosome Data

Number of Associations	0	1	2	3

the beta-binomial and finite-mixture distributions provide reasonable fits to this problem.

Table 6 shows the distribution of the number of chromosome associations for 337 nuclei. We fit three distributions to these data: the binomial, the beta-binomial, and the finite-mixture. The maximum likelihood results of fitting these distributions are given in **Table 7**.

As we can see in this example, the two extra variation distributions produce almost identical results. The variance estimates under the beta-binomial and the finite-mixture distributions are 1.17 times the estimate obtained by using the binomial distribution. This value is an estimate of the multiplier $\{1 + \rho^2(m - 1)\}$ that appears in Eq. (2). To test for the presence of extra variation under a specific overdispersion model, we need to test the hypothesis $H_0: \rho = 0$ versus the alternative hypothesis $H_1: \rho > 0$. Properties of the likelihood ratio test cannot be obtained by the usual asymptotic theory since the parameter being tested is on the boundary of the parameter space, $0 < \rho < 1$. Self and Liang^[48] have shown that in this case (see case 5 in their paper), the asymptotic distribution of the likelihood ratio test is a 50:50 mixture of a point mass at zero and at a chi square distribution with 1 degree of freedom. The likelihood ratio test statistic is 7.2 under the beta-binomial and 7.0 under the finite-mixture, with p -values approximately 0.004. These statistics are almost the same, and they strongly support the hypothesis of extra variation under either model.

To conclude this example, we compute the traditional Pearson's goodness-of-fit chi square test $X^2 = \sum_{s=0}^3 (O_s - E_s)^2 / E_s$ to see if either distribution is appropriate for the data. **Table 8** shows the observed and expected frequencies of the number of associations under the three distributions considered in this example. The binomial distribution does not fit the data well, given that $X^2 = 8.11$, with an associated p -value of 0.017. The beta-binomial and the finite-mixture distributions fit the distribution of the number of associations fairly well, with P -values of the chi square goodness-of-fit tests being 0.383 and 0.348, respectively.

Neerchal and Morel^[49] investigated the “relative asymptotic efficiency” of the quasi-likelihood estimator given in Eqs. (17)–(19) with respect to the maximum likelihood estimate of π of the beta-binomial and finite-mixture distributions. The relative efficiency of the quasi-likelihood estimator relative to the maximum likelihood estimator of π under the beta-binomial is

$$\frac{\pi(1-\pi)\phi}{\frac{nm}{V(\hat{\pi}_{bb})}}$$

where $\phi = \{1 + \rho^2(m - 1)\}$, $\hat{\pi}_{bb}$ is the maximum likelihood estimator of π under the beta-binomial distribution and $V(\hat{\pi}_{bb})$ is the asymptotic covariance matrix when the cluster size m is large. The relative asymptotic efficiency with respect to the finite-mixture distribution is defined in a similar way. **Table 9** shows the asymptotic relative efficiencies for the combinations $\pi = 0.1, 0.3, 0.5$; $\rho^2 = 0.09, 0.25, 0.49$; and $m = 10, 40$. The results from **Table 9** indicate

		Finite mixture	4.05	4.05	4.05

that there is little gain in efficiency in using the beta-binomial distribution over the quasi-likelihood model. The two distributions for modeling extra variation have essentially the same efficiency of the quasi-likelihood estimator when $\rho^2 = 0.09$ and $m = 10$. But as ρ^2 increases and/or the cluster size m gets larger, the gain in efficiency of the finite-mixture distribution over the quasi-likelihood model becomes greater.

We now revisit the teratology example of Table 2 and fit the beta-binomial and finite-mixture models, assuming a common intra-litter correlation ρ^2 and the logistic link with a full factorial design. The results of the fittings are giving in Table 10. As we can see from Table 10, the results of the beta-binomial and finite-mixture models are very consistent with each other. The negative coefficients indicate an increased risk of no ossification. Thus, the toxic effect of the chemicals is to impede ossification. If $\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3$ represent, respectively, the beta estimates for Intercept, TCPO, PHT, and TCPO + PHT, then an approximate 95%

confidence interval for the odds ratio of PHT versus the combined controls when TCPO = 0 mg/kg is given by $e^{\hat{\beta}_2 \pm 1.96 \sqrt{\hat{v}(\hat{\beta}_2)}}$, where $\hat{v}(\hat{\beta}_2)$ represents the estimated asymptotic variance of $\hat{\beta}_2$. Similarly, an approximate 95% confidence interval for the odds ratio of PHT versus the combined controls when TCPO = 100 mg/kg is given by $e^{(\hat{\beta}_2 + \hat{\beta}_3) \pm 1.96 \sqrt{\hat{v}(\hat{\beta}_2 + \hat{\beta}_3)}}$. Table 11 shows the approximate 95% confidence intervals for the two levels of TCPO based on the beta estimates of the binomial, single-inflation-factor and Williams's^[5] approach in Table 3 and the beta estimates based on the beta-binomial and finite-mixture models in Table 10. Recall single-inflation factor was estimated by computing the deviance over its degrees of freedom. The confidence intervals under the binomial model are much shorter than for all the extra-variation models. This suggests that the level of confidence obtained under the binomial model is below the nominal one. The remaining models, which incorporate the litter effect, suggest that in the presence of TCPO, the chances to impede ossification may be the same for both PHT and the combined control.

A GOODNESS-OF-FIT TEST FOR EXTRA VARIATION MODELS

Tests for goodness-of-fit with extra variation models have typically focused on testing for the presence of extra variation in the data rather than model adequacy. Paul and Plackett,^[50] and Collings and Margolin,^[51] describe a variety of statistics for testing the null hypothesis that there is no overdispersion against specific alternatives such as the beta-binomial model. They consider likelihood functions that reduce to “no extra variation” when the extra variation parameter is zero. An illustration of such a test for overdispersion was given in “Likelihood Models,” when we tested the hypothesis $H_0 : \rho = 0$ versus the alternative hypothesis $H_1 : \rho > 0$ under either the beta-binomial and finite-mixture model, for the teratology data of Table 2. Note that the construction of goodness-of-fit tests for testing the adequacy of a specific extra variation model is straightforward if the

clusters sizes are the same, that is, $m_j \equiv m$, for $j = 1, 2, \dots, n$. This is the case of the chromosome example in “Likelihood Models” (Table 8), where the traditional goodness-of-fit test given in Rao (^[52], pages 391–398) and Cramer (^[53], pages 477–506) applies. When the m_j ’s are different, the construction of a Pearson’s goodness-of-fit statistic is not straightforward because the observed and expected frequencies are not associated with a unique value of m . Neerchal and Morel^[49] proposed an extension of the traditional Pearson’s chi-square statistic $X^2 = \sum_{s=0}^3 (O_s - E_s)^2 / E_s$ when the clusters sizes m_j ’s are allowed to be different. Asymptotic properties of this test, as well as extensions to the case where covariates are available, have been investigated by Sutradhar^[54] and Sutradhar et al.^[55]

Let $t_1, t_2, \dots, t_n$ represent a realization of n -independent random variables $T_1, T_2, \dots, T_n$, these variables assumed to have extra variation relative to the binomial distribution, that is, the first two moments are as in Eqs. (1) and (2). It is hypothesized that each T_j has a certain probability function depending on the parameters π, ρ , and the cluster size m_j , where the m_j ’s are allowed to be distinct. One way of extending the traditional Pearson’s statistic is by pooling the data across all clusters and comparing the observed distribution of t_j/m_j to the corresponding expected frequencies. To this end, first divide the unit interval into k mutually exclusive interval $A_s, s = 1, 2, \dots, k$. Then, compute the observed and expected frequencies as

$$O_s = \sum_{j=1}^n I\left(\frac{t_j}{m_j} \in A_s\right)$$

and

$$E_s = \sum_{j=1}^n \sum_{t=0}^{m_j} \Pr(T_j = t) I\left(\frac{t}{m_j} \in A_s\right)$$

where $I(\cdot)$ represents an indicator function and $\Pr(T_j = t)$ is based on the maximum likelihood estimates of π and ρ . An example of this test with varying m_j ’s can be found in Neerchal and Morel.^[49] They fit the beta-binomial and finite-mixture distributions to three data sets from a study to induce mutagenic damage previously analyzed

by Haseman and Soares.^[56] In the study, a group of male mice were first treated with a suspected mutagen and later paired with one or more untreated females. The female mice became pregnant and after a certain time they were sacrificed and their uteri examined for the presence of living and dead implantations. (An implantation is an early stage of a fetus.) Because implantations or fetuses from the same mother tend to respond similarly, it is reasonable to treat them as a natural cluster. Table 12 depicts the results of the goodness-of-fit test for one of the three data sets ($n = 554$). For this data set the average clusters size was 13.1, with cluster sizes varying between 1 and 18. The p -values of the goodness-of-fit test under the beta-binomial and finite-mixture distributions were 0.0014 and 0.2205 respectively. These tests are based on six degrees of freedom. It is clear that for this example, the finite-mixture distribution fits the data well while the beta-binomial distribution does not. The p -values were also estimated by bootstrapping the data parametrically with 20,000 replications. They turned to be 0.0012 and 0.2124, close to the ones obtained by using the chi-square distribution.

GENERALIZED ESTIMATING EQUATIONS

“Generalized Estimating Equations,” better known as GEE or GEEs, is a methodology adapted by Liang and Zeger,^[31] and Zeger and Liang^[32] for the analysis of longitudinal data when regression is the main focus. The methodology is related with quasi-likelihood models (Wedderburn^[42] and McCullagh^[57]) and generalized linear models (McCullagh and Nelder^[58]). Although the GEE methodology was originally proposed for longitudinal data analysis, it has been applied to almost any type of clustered data. In the forthcoming discussion we restrict ourselves to binary responses or counts. However the methodology can be extended to

Table 12 Goodness-of-Fit Results for Haseman and Soares^[54] Data ($n = 554$)

multinomial outcomes. For each subject j , $j = 1, 2, \dots, n$, let $\mathbf{Y}_j = (y_{j1}, y_{j2}, \dots, y_{jm_j})^t$ represent a m_j -dimensional column vector of responses, and let $\mathbf{X}_j = (x_{j1}, x_{j2}, \dots, x_{jm_j})^t$ denote an associated $m_j \times k$ matrix of observed covariates, where x_{jl} , $l = 1, 2, \dots, m_j$, represents a k -dimensional row vector. Let μ_{jl} and $v(\mu_{jl})$ represent, respectively, the mean and the “natural variance” of y_{jl} , the latter being the variance of the y_{jl} ’s when they are independent and belong to the exponential family. If the y_{jl} ’s were either binomial or Poisson distributed, their corresponding natural variances would be $\pi_{jl}(1 - \pi_{jl})$ or λ_{jl} , respectively. It is further assumed that the μ_{jl} ’s are related to the x_{jl} ’s throughout a link function $g(\cdot)$ such that $g(\mu_{jl}) = x_{jl}\beta^0$, where β^0 is a k -dimensional column vector of unknown parameters. The canonical links for the binomial and Poisson distributions are the logit and logarithmic functions, respectively. Other links for the binomial distribution are the “identity,” the “probit” and the “complementary log-log” functions. The identity function may be used as a link function for the Poisson case.

Let $\mathbf{A}_j$ represent the $m_j \times m_j$ diagonal matrix of natural variances of the vector $\mathbf{Y}_j$, $\mathbf{A}_j = \text{diag}\{v(\mu_{j1}), v(\mu_{j2}), \dots, v(\mu_{jm_j})\}$. In order to apply the GEE methodology one needs first to define the correlation structure of $\mathbf{Y}_j = (y_{j1}, y_{j2}, \dots, y_{jm_j})^t$ through an $m_j \times m_j$ “working” correlation matrix $\mathbf{R}_j(\alpha)$ such that

$$\mathbf{V}_j = \mathbf{A}_j^{1/2} \mathbf{R}_j(\alpha) \mathbf{A}_j^{1/2} \phi \quad (25)$$

would be equal to the variance-covariance matrix of $\mathbf{Y}_j$, if $\mathbf{R}_j(\alpha)$ were the true correlation matrix for the $\mathbf{Y}_j$ ’s. Then define the estimating equations as

$$\sum_{j=1}^n \mathbf{D}_j^t \mathbf{V}_j^{-1} (\mathbf{Y}_j - \mu_j) = \mathbf{0} \quad (26)$$

where $\mu_j = (\mu_{j1}, \mu_{j2}, \dots, \mu_{jm_j})^t$, $\mathbf{D}_j^t$ represents the $k \times m_j$ matrix of first derivatives of μ_j with respect to β^0 , and $\mathbf{V}_j$ is defined as in Eq. (25).

In order to solve the estimating Eq. (26) for β^0 , consistent estimators of ϕ and α (say, $\hat{\phi}$ and $\hat{\alpha}$) are needed. These estimators are functions of the data and of β^0 . So they can be acquired by first obtaining $\hat{\beta}$, the solution of estimating Eq. (26) assuming that $\mathbf{R}_j(\alpha)$ is an identity matrix and that ϕ is equal to 1. Then $\hat{\phi}$ and $\hat{\alpha}$ are plugged into the estimating Eq. (26), which is then solved to obtain an improved version of $\hat{\beta}$. The improved version of $\hat{\beta}$ incorporates the hypothesized covariance matrix structure given in Eq. (25) and can be used to obtain new estimators $\hat{\phi}$ and $\hat{\alpha}$. The procedure continues until no changes are observed on $\hat{\beta}$, $\hat{\phi}$, and $\hat{\alpha}$. Liang and Zeger^[31] have shown the consistency of $\hat{\beta}$ under mild regularity conditions. They also showed that a consistent estimator of the variance-covariance matrix of $\hat{\beta}$

$$\tilde{\mathbf{A}} = \left\{ \mathbf{H}(\hat{\beta}, \hat{\alpha}, \hat{\phi}) \right\}^{-1} \mathbf{G} \left\{ \mathbf{H}(\hat{\beta}, \hat{\alpha}, \hat{\phi}) \right\}^{-1} \quad (27)$$

where $\mathbf{H}(\hat{\beta}, \hat{\alpha}, \hat{\phi}) = \sum_{j=1}^n \mathbf{D}_j^t(\hat{\beta}) \mathbf{V}_j^{-1}(\hat{\beta}, \hat{\alpha}, \hat{\phi}) \mathbf{D}_j(\hat{\beta})$, $\mathbf{G} = \frac{(n^* - 1)}{(n^* - k)} \frac{n}{(n - 1)}$

$$\sum_{j=1}^n (d_j - \bar{d})(d_j - \bar{d})^t, \quad n^* = \sum_{j=1}^n m_j, \quad d_j = \mathbf{D}_j^t(\hat{\beta}) \mathbf{V}_j^{-1}(\hat{\beta}, \hat{\alpha}, \hat{\phi})$$

$\mathbf{Y}_j - \mu_j(\hat{\beta})$, and $\bar{d} = \sum_{j=1}^n d_j / n$. Usually the matrix $\mathbf{G}$ does not

contain the multiplier $(n^* - 1)/(n^* - k)$ and some authors treat $\bar{d}$ as a null vector. If each cluster contains exactly one elemental unit, the factor $\frac{(n^* - 1)}{(n^* - k)} \frac{n}{(n - 1)}$ reduces to $n/(n - k)$, which is the degrees of freedom correction applied to the residual mean square for ordinary least squares in which k parameters are estimated. The quantity $(n^* - 1)/(n^* - k)$ reduces the small sample bias associated with using the estimated link function to calculate deviations. For large samples, the variance-covariance $\tilde{\mathbf{A}}$ in Eq. (27) provides correct Type I error rates for arbitrary choice of the working correlation matrix $\mathbf{R}_j(\alpha)$. This is one of the most interesting characteristics of GEE: the inferences based on $\hat{\beta}$ are correct as far as one uses the “robust” (also known as “sandwich” or “empirical”) variance-covariance matrix given in Eq. (27).

This is under the assumption that the mean of the model has been correctly estimated. Liang and Zeger^[31] provide results of a simulation study where they show gains in efficiency when the working correlation matrix coincides with the true and unknown one. Some examples of working correlation matrices are: independence, exchangeable, m -dependent, first-order autoregressive, and unspecified. For each of these cases, Liang and Zeger^[31] provide indications on how to estimate ϕ and α .

It is well known that use of the estimated variance-covariance matrix given in Eq. (27) in the construction test of Wald’s statistics leads to inflated Type I errors in small samples. Morel,^[59] Morel, Bokossa and Neerchal,^[60] and Morel and Neerchal,^[61] have proposed a modified version of in Eq. (27) to reduce the small sample bias. The modified variance-covariance matrix is asymptotically equivalent to the one defined in Eq. (27). The small sample correction is given by

$$\hat{\mathbf{A}} = \hat{\mathbf{A}} + \hat{\delta}_n \hat{\phi} \left\{ \mathbf{H}(\hat{\beta}, \hat{\alpha}, \hat{\phi}) \right\}^{-1} \quad (28)$$

where $\tilde{\mathbf{A}}$ is defined as in Eq. (27), $\hat{\phi} = \max\{1, \text{trace}\{(\mathbf{H}(\hat{\beta}, \hat{\alpha}, \hat{\phi}))^{-1} \mathbf{G}\} / v\}$, and $\hat{\delta}_n = \min\{0.5, v/(n - v)\}$. The quantity $\hat{\phi}$ is an estimate of the design effect, which has been bounded below by 1. The factor $\hat{\delta}_n$ converges to zero as the sample size increases, and has been bounded above by 0.5. The upper bound on $\hat{\delta}_n$ is arbitrary and usually does not come into place when sample sizes are moderate. It has been demonstrated in Monte Carlo studies that the variance-covariance matrix in Eq. (28) reduces the inflated Type error rates due to small samples. We recommend the use of the modified estimator in practice. This adjusted

variance estimator falls into the category of “additive correction” and it is always positive definite provided $\tilde{A}$ in Eq. (28) is. Other small sample bias corrections have been proposed by Fay and Graubard^[62] and Mancl and DeRouen.^[63]

Let us now consider the ossification data of Table 2. These data were used to illustrate the fitting of two quasi-likelihood models in “Quasi-likelihood Models,” and the fitting of two likelihood models in “Likelihood Models.” We fit these data using the GEE methodology with an “independence” working correlation matrix. These results, which are reported in Table 13, illustrate the use of the Morel-Bokossa-Neerchal small sample bias correction. The adjusted standard errors are slightly larger to correct for the small sample bias correction embedded in the “sandwich.” As the number of clusters n increases, this correction vanishes.

Liu and Liang^[64] present a method for computing sample size and power for studies with correlated observations. The term “sample size” refers to the number of clusters in which the cluster is formed by individuals in longitudinal studies and by families in family studies. The sample size determination is based on the GEE methodology and a quasi-score test statistic. We will next consider two important special cases namely the two-sample problem with correlated binary responses, and the case of a cross-over design with binary responses.

In the two-sample problem two independent treatment groups are considered. Let P_1 and P_2 represent their hypothesized proportions. Let ρ represent the intra-cluster correlation and m the number of repeated (correlated) measurements. At a α level and a $1 - \beta$ power, an estimate of the sample size n (number of clusters) is given by

$$n = \frac{(Z_{\beta} + Z_{\alpha/2})^2 \{P_1(1 - P_1) + P_2(1 - P_2)\} \{1 + \rho(m - 1)\}}{(P_1 - P_2)^2 m} \quad (29)$$

Here Z_p represents the upper p -th percentile of a standard normal distribution.

As an example, consider a dental care study for the detection of caries. Children used a tooth paste containing as

active ingredient either stannous fluoride or sodium fluoride for three years. The estimated proportions of observing caries for stannous fluoride and sodium fluoride were respectively 9.8% and 8.6%. The corresponding odds ratio is 1.15 (relative risk is 1.14). The average number of teeth surfaces investigated were approximately $m = 110$ surfaces per subject. Furthermore, an estimate of the “design effect” $\{1 + \rho(m - 1)\}$ turned out to be 5.50. A new study is being planned to establish the superiority of sodium fluoride over the active ingredient stannous fluoride. Assuming a power of 82% and a Type I error rate of 10% (5% for a one-sided test), then using Eq. (29) the estimated sample size is $n = 380$ subjects per treatment group.

Consider now a 2×2 cross-over design, that is, two treatments (denoted by A and B, say) and two periods. Subjects are randomly allocated to one of the sequences AB and BA. That is, half of the subjects receive treatment A during the first period, and then treatment B during the second period. The order of application for subjects in the BA sequence is reversed. Let P_1 and P_2 represent the success rates of treatments A and B, respectively. Let ρ represent the correlation of responses between the two periods. At a α level and a $1 - \beta$ power, an estimate of the sample size n is

$$n = \frac{(Z_{\alpha/2} + Z_{\beta})^2 \{P_1(1 - P_1) + P_2(1 - P_2) - 2\rho\sqrt{P_1(1 - P_1)P_2(1 - P_2)}\}}{(P_1 - P_2)^2} \quad (30)$$

Here n stands for the total number of subjects in the study, thus half of the sample size n should be allocated to the sequence AB and the other half to BA. As an example, consider a clinical 2×2 crossover study where a test compound to treat sleep disorders will be compared against a placebo. The trial consists of two nights with a proper wash out in between nights. The primary endpoint is if the subject experienced weakness after the onset of sleep. The proportion of subjects experiencing weakness without any medication is believed to be $P_1 = 0.80$. Researchers expect to reduce this rate to $P_1 = 0.50$ when subjects are on active. From previous studies, researchers expect the correlation

Table 13 Beta Estimates and Standard Errors of Ossification Data for Full Factorial Logistic Regression Model Using GEE with Independence Working Correlation Matrix and with the Morel-Bokossa-Neerchal Correction

Parameter	Model		
	GEE with independence working correlation matrix		GEE with Morel-Bokossa-Neerchal Correction
	Estimate	Standard error	Standard Error
Intercept	0.83	0.25	0.26
TCPO	−0.85	0.41	0.43
PHT	−2.11	0.34	0.37
TCPO+PHT	1.05	0.76	0.80

PHT: phenytoin; TCPO: trichloropropene oxide.

ρ is approximately $\rho = 0.05$. Using Eq. (30), for a two-sided test with 5% Type I error rate and 90% power the estimated number of subjects for the 2×2 cross-over is about $n = 46$.

RANDOM EFFECT MODELS

The Generalized Linear Models (GLM) framework provided by McCullagh and Nelder^[1] unifies the analysis of continuous and discrete response variables when the responses can be assumed to be independent. As previously discussed, in GLM, moments of the response y_{ji} , from the i -th elemental unit from the j -th cluster, $j = 1, 2, \dots, n$, $i = 1, 2, \dots, m_j$, are modeled such that $E(y_{ji}) = \mu_{ji}$ and $V(y_{ji}) = \phi v(\mu_{ji})$, where μ_{ji} depends on a k -dimensional row vector of known covariates $\mathbf{x}_{ji}$ and an unknown k -dimensional column vector of unknown parameters $\boldsymbol{\beta}^0$ through a link function $g(\cdot)$ such that $g(\mu_{ji}) = \mathbf{x}_{ji}\boldsymbol{\beta}^0$. As before, $v(\mu_{ji})$ is a known function that gives the variance of the observation in terms of the mean. As described in “Quasi-likelihood Models,” GLM formulation is closely related to the quasi-likelihood method of obtaining the estimates. However, the quasi-likelihood method does not facilitate the simultaneous estimation of the mean (μ) and dispersion (ρ) parameters in the extra variation models. The GLM framework has been extended by Zeger, Liang, and Albert^[40] to include random effects. The resulting models, *generalized linear mixed models* (GLMM), can accommodate the analysis of longitudinal data, where subjects are monitored over a period of time, and the analysis of observations obtained on different subjects belonging to some kind of cluster, like those usually obtained in cluster sampling. As indicated earlier, overdispersed binomial (or multinomial) is usually a result of natural association among observations from individuals belonging to the same cluster. Thus, we include a brief review of GLMM in this chapter.

Extension of GLM to obtain GLMM is straightforward and is analogous to the extension of linear models to linear mixed models. A random effect is introduced corresponding to each subject, which describes the deviation of the subject's response from the group average. We consider only the simplified case of subjects treated as random. Real life examples might be more complex. For instance, in a multi-center study where subjects within centers provide repeated measurements across time, it would be reasonable to treat “centers” and “subjects within centers” as random. Following the previous notations, under GLMM, the response y_{ji} for the i -th elemental unit in the j -th cluster is assumed to satisfy

$$g(\mu_{ji}) = \mathbf{x}_{ji}\boldsymbol{\beta}^0 + z_{ji}b_j \quad (31)$$

and

$$\text{Var}(y_{ji}|b_j) = \phi v(\mu_{ji}) \quad (32)$$

where $\mu_{ji} = E(y_{ji} | b_j)$ is an independent observation from a mixture distribution. Note that conditional on b_j , Eqs. (31) and (32) describe a GLM with link function $g(\cdot)$ and variance function $v(\cdot)$. Unconditional moments may be obtained by taking expectations of the conditional moments given by Eqs. (31) and (32) with respect to the distribution of b_j 's. Thus under GLMM,

$$\mu_{ji} = E(y_{ji}) = E\{E(\mu_{ji} | b_j)\} = \int g^{-1}(\mathbf{x}_{ji}\boldsymbol{\beta}^0 + z_{ji}b) \partial F(b_j) \quad (33)$$

and

$$\begin{aligned} V(y_{ji}) &= E\{V(y_{ji}|b_j)\} + V\{E(y_{ji}|b_j)\} \\ &= \int \phi V\{g^{-1}(\mathbf{x}_{ji}\boldsymbol{\beta}^0 + z_{ji}b_j)\} \partial F(b_j) + z_{ji}z_{ji}'\sigma_b^2 \end{aligned} \quad (34)$$

Models described by Eqs. (33) and (34) are referred to as *population average* (PA) models by Zeger, Liang, and Albert.^[40] They refer to the models given by Eqs. (31) and (32) as *subject specific* (SS) models. Such models are most suitable when response for an individual (rather than description of the population as a whole) is the focus of the study, as in studies of growth curves. Population-average models are most useful in epidemiological studies. Here the focus is in studying the difference between the average responses of groups. A salient example given by Zeger, Liang, and Albert^[40] is as follows: Suppose x_{ji} indicates whether or not the subject j at time i smokes and y_{ji} is the presence or absence of a respiratory infection. Then the PA model describes the difference in infection rates between smokers and non-smokers, whereas the SS model estimates the expected change in the probability of infection of a subject given a change in smoking behavior.

Estimation of a GLMM can be done, in principle, by specifying a distribution for the random effects b_j 's, obtaining (by integration) the marginal (unconditional) likelihood of the data and then proceeding with likelihood estimation. Even in the case of linear mixed models, closed form for likelihood estimates may not be available. Harville^[65] implements this approach to the linear mixed models, assuming a normal distribution for the random effects and a normal distribution for the data conditional on the random effects. Anderson and Aitkin^[66] and Im and Gianola^[67] use maximum-likelihood estimation in logistic and probit models, where random effects are assumed to follow a normal distribution and the conditional distribution response is binomial. In general, being able to obtain likelihood estimates for GLMM, depends on whether or not the marginal (unconditional) distribution of the y_{ji} 's can be obtained by integrating with respect to a justifiable distribution of the random effects. Zeger and Karim^[37] use the connection between GLMM and the Bayesian framework to give a method of estimation that overcomes the computational limitations using a Gibbs sampling

approach. One way of avoiding numerical computation of these integrals is to approximate the integrals by simple expansions or a method such as Laplace's method of approximating integrals. This approach has been explored by Stiratelli et al.^[68] and Breslow and Clayton^[35]. Zeger, Liang, and Albert^[40] use the generalized estimating equations approach to estimate GLMM. Schall^[39] gives an algorithm for estimation in GLMM which is easy to program. This algorithm also accommodates the specification of just the first two moments of the distribution of the random effects. Drum and McCullagh^[34] adapt the residual maximum-likelihood (REML), a method that has been successfully used in linear mixed models, to GLMM with logistic links. Their [Table 1](#) gives a succinct summary of methods used in estimating GLMM. We now provide an example.

Beitler and Landis^[69] analyzed data from a multicenter randomized clinical trial aimed to investigate the efficacy of two topical cream preparations (active drug and control) in curing an infection. The data are provided in [Table 14](#).

We consider the following logistic model with random effects (clinics as random).

$$t_{ij} \text{ given } (x_{ij}; b_j) \sim \text{Binomial}(\pi_{ij}; m_{ij})$$

$$\text{logit}(\pi_{ij}) = \beta_0 + \beta_1 x_{ij} + b_j$$

$$x_{ij} = 1 \text{ if } i = 1 \text{ (subjects receiving the drug), zero otherwise}$$

$$b_j \text{'s independent and identically distributed Normal } (0, \sigma^2)$$

Table 14 Favorable Responses to Active Drug and Control Treatment from a Multicenter Randomized Clinical Trial

Clinic	Treatment	Favorable responses	Total
1	Drug	11	36
1	Control	10	37
2	Drug	16	20
2	Control	22	32
3	Drug	14	19
3	Control	7	19
4	Drug	2	16
4	Control	1	17
5	Drug	6	17
5	Control	0	12
6	Drug	1	11
6	Control	0	10
7	Drug	1	5
7	Control	1	9
8	Drug	4	6
8	Control	6	7

Here the subscript i , $i = 1, 2$ represents the cream preparation ($i = 1$ active drug, $i = 2$ control). The centers are represented with the subscript j , $j = 1, 2, \dots, 8$. We fit the previous GLMM to the multicenter data using the Laplace method. The maximum likelihood results are provided in [Table 15](#).

The active drug effect is significant at the customary 5%. The estimated odds-ratio turned out to be $e^{0.7382} = 2.09$. An approximate 95% for the odds-ratio is (0.03, 1.45).

We conclude the discussion of GLMM with a few general remarks. GLMM methodology provides useful ways of modeling clustered responses, which occur routinely in biopharmaceutical studies. Responses from subjects who belong to the same neighborhood and responses collected from the same subject over a period of time in a longitudinal research are examples of such data. As seen in "Likelihood Models," the extra variation models presented in this chapter, namely, the beta-binomial models and finite-mixture models, can, in fact, be considered as random effect models. However, it should be noted that the models described in this chapter focus on situations where responses from elemental units within the cluster are not available.

SUMMARY

In this chapter, we presented a description of the phenomenon known as extra variation or overdispersion, along with a review of the literature. There are four different sections, each section describing a different approach for modeling extra variation. These sections are "Quasi-Likelihood Models," "Likelihood Models," "Generalized Estimating Equations Models," and "Random Effect Models." Another section was devoted to a goodness-of-fit statistic for testing the adequacy of overdispersion models. Several examples discussing a variety of real data sets are cited. Quasi-likelihood models are illustrated with data from two clinical studies (pH data of [Table 1](#) and vertebral fracture data of [Table 4](#)) and one preclinical experiment (ossification data of [Table 2](#)). In the section of likelihood models, two distributions for modeling extra variation are presented, namely, the beta-binomial and the finite-mixture. An insightful representation of the finite-mixture model is provided ([Fig. 1](#)). An example on chromosome association is thoroughly discussed ([Table 6](#)), and the example on ossification data of [Table 2](#) is revisited.

Table 15 Maximum Likelihood Results Using the Laplace Method from a Multicenter Randomized Clinical Trial

Parameter	Estimate	Standard error	p-value
Intercept (β_0)	-1.1965	0.55291	0.0672
Drug Effect (β_1)	0.7382	0.3004	0.0436
Variance due to clinics (σ^2)	1.9313	1.16873	
-2* Log Likelihood	74.20		

The sections on generalized estimating equation models and random effect models are clearly presented. The ossification data of Table 2 is used one more time to illustrate the use of the generalized estimating equations approach as well as a small sample bias correction usually embedded into the sandwich estimator. An epidemiological example is described in the section of random-effect models to clarify the difference between population-average models and subject-specific models. An example (Table 14) of a GLMM application using the Laplace estimation method is presented. In practice, overdispersion may be far too common than one would anticipate and therefore we recommend that one should always check for the presence of overdispersion before proceeding with the analysis under the assumption of independence.

Abstract

The goal of factor analysis is data reduction of multiple measurements into a smaller number of latent outcomes or factors that are not directly observable. This entry provides some general background information on factor analysis and discusses the standard methods of in practice for continuous data.

Keywords: Correlation; Data reduction; Latent trait; Measurement model; Multivariate analysis.

INTRODUCTION

Factor analytic methods are among a rich body of literature on statistical methods for multivariate continuous outcomes. The goal of factor analysis is data reduction of multiple measurements into a smaller number of latent outcomes or factors that are not directly observable. The factors are derived via a decomposition of the covariance or correlation matrix of the observed, often called manifest, data. We begin with a brief overview of the controversial origin of this method; describe the standard methods in practice for continuous data; discuss extensions of these methods to data with other distributions assumed; and present an example. We conclude with some discussion and description of further methodological extensions.

BACKGROUND

The development of factor analysis was first attributed to Spearman, who sought to measure “intelligence.”^[1] Although it is often taught as purely deductive mathematics,^[2] this method was derived with the above goal in mind. A student of Spearman’s, Cyril Burt, is credited with the reification of intelligence, that is, utilizing this method to justify his theory about the heritability of intelligence and to derive a unilinear ranking system. Unable to resist human nature, these rankings have been used to discriminate against various subgroups of society. In addition, controversy arose when Thurstone published his work entitled “Vectors of Mind,”^[3] which illustrated the non-uniqueness of Spearman’s principal factors (principal components solution), and proposed rotation of the

factors to identify “logical” vectors. This approach challenged Spearman’s theory that the first principal factor was “general intelligence.” As the two solutions explained an equivalent proportion of the sample variability, both models are equally plausible.

Despite its checkered past, factor analysis has maintained its popularity in the social sciences.^[4] In health research, measurement of abstract concepts such as “quality of life” or “depression” are of interest. While these concepts are generally measured via questionnaires, others have used them to discern structure from biological parameters, such as quantifying the severity of birth defects,^[5] to identify a metabolic syndrome,^[6] and to evaluate the impact of different types of pollution on mortality.^[7] Even when it is hard to justify the theoretical existence of a “latent variable,” these summary scores can be considered logical constructs of the observed data.^[8] There are two approaches to the implementation of factor analysis. The first, termed exploratory, has the goal of identifying the latent structure that is data driven. Confirmatory factor analysis (CFA) begins with a theoretic framework or proposed structure, which is then confirmed by evaluating goodness-of-fit to the observed data. Both frameworks are described below.

EXPLORATORY FACTOR ANALYSIS

Theoretic Model

Exploratory factor analysis (EFA) aims to partition the covariance matrix of the data into two components, a piece that is common to all the measures (or variables), and a piece which is specific to each measurement. In truth,

the underlying structure is unknown. Let $\mathbf{X} = (x_1, \dots, x_p)'$ be a p -variate random (column) vector with mean $\mu = (\mu_1, \dots, \mu_p)'$ and covariance matrix $\Sigma = [\sigma_{ij}]_{p \times p}$. The vector $\mathbf{X}$ is assumed to be linearly dependent on a set of $m < p$ random, unobserved common factors $\mathbf{f} = (f_1, \dots, f_m)$, plus residual or specific factors $\boldsymbol{\varepsilon} = (\varepsilon_1, \dots, \varepsilon_p)$. Further, assume $E(\mathbf{f}) = \mathbf{0}$, $\text{cov}(\mathbf{f}) = \mathbf{I}$, $E(\boldsymbol{\varepsilon}) = \mathbf{0}$, $\text{cov}(\boldsymbol{\varepsilon}) = \Psi = \text{diag}(\Psi_1, \dots, \Psi_p)$, and $\text{cov}(\mathbf{f}, \boldsymbol{\varepsilon}) = \mathbf{0}$. Then $\mathbf{X} - \mu = \mathbf{L}\mathbf{f} + \boldsymbol{\varepsilon}$ where $\mathbf{L} = [l_{ij}]_{p \times m}$ is a matrix of factor “loadings” or regression weights. The resulting covariance matrix is

$$\begin{aligned}\Sigma &= \mathbf{L}\mathbf{L}' + \Psi \\ \Rightarrow \sigma_{ii}^2 &= \sum_{k=1}^m l_{ik}^2 + \Psi_i = h_i^2 + \Psi_i\end{aligned}$$

The variance of the i th variable explained by the common factors is called the i th communality, h_i^2 , while Ψ_i is called the unique or specific variance. The above model can easily be generalized so that the common factors are intercorrelated by assuming $\text{cov}(\mathbf{f}) = \Phi \neq \mathbf{I}$. In this case the factors are said to be oblique. When $\text{cov}(\mathbf{f}) = \mathbf{I}$, the factors are said to be orthogonal.

A basic property of EFA is that it is scale independent. That is, if $\mathbf{A}$ is an orthogonal matrix, then $\mathbf{A}\mathbf{X}$ will have loadings $\mathbf{A}\mathbf{L}$ and factors $\mathbf{f}$. Another key property is that $\mathbf{f}$ and $\mathbf{L}$ are not unique except when the dimension of $\mathbf{f}$ is one. So, $\mathbf{L}\mathbf{f} = \mathbf{L}\mathbf{T}\mathbf{T}'\mathbf{f}$ for any $m \times m$ orthogonal matrix $\mathbf{T}$. This non-uniqueness property leads to the idea of factor rotation.

Parameter Estimation

Let $\mathbf{x}_1, \dots, \mathbf{x}_n$ be a sample of size n observations of random vector $\mathbf{X}$. The factors and loadings are derived from the sample covariance matrix $\mathbf{S}$, an estimator of the true variance/covariance matrix Σ . That is, the estimated EFA model is found by solving $\mathbf{S} = \hat{\mathbf{L}}\hat{\mathbf{L}}' + \hat{\Psi}$. As the estimates for $\mathbf{L}$ and Ψ ($\hat{\mathbf{L}}$ and $\hat{\Psi}$ respectively) are not unique, initial solutions are obtained by imposing further constraints. The most popular methods for obtaining the initial solution are the principal component, principal factor, and maximum likelihood. The solution from any method is then rotated for ease of interpretation. Ideally, each variable will have a high loading on only one factor. One of the most common rotations is the varimax rotation,^[9] which selects the orthogonal matrix $\mathbf{T}$ that maximizes the sum of variances of the squared loadings of each factor. That is, it attempts to have only large or negligible coefficients in any column of the rotated loadings matrix $\hat{\mathbf{L}}$. Other orthogonal rotations include the quarimax and equamax rotations. Oblique rotations, while not orthogonal, can often be easier to interpret but result in correlated factors. One example is the PROMAX rotation,^[10] which takes orthogonally rotated factors (usually the varimax rotation) and rotates them again to oblique factors that approximate a target matrix $\mathbf{Q}$. $\mathbf{Q} = [q_{ij}]_{p \times m}$ is structured such that $q_{ij} = |l_{ij}^{-1}| l_{ij}$ where $r > 1$ is the power of the rotation. Oblique

factors have been demonstrated to replicate better than orthogonal solutions.^[11]

Number of Factors

An important issue is how many factors to include in the model, as different m 's will lead to different solutions and interpretations. Parameter estimation is accomplished conditional on a pre-specified number of factors. When the population is normally distributed, a likelihood ratio test^[12] can be used to test the adequacy of the choice of the number of factors. However, this test can lead to overfitting, that is, selecting an m such that the final factor(s) may be “significant” but provide no additional insight into the data. A number of ad hoc methods have also been proposed. These include using factors with unrotated eigenvalues greater than one, factors that account for approximately 70%–80% of the original variation in the data, and factors with “large” values on a scree plot of the sample eigenvalues of $\mathbf{S} - \Psi$. The term “scree” refers to the debris that falls off the mountain and collects at its base. Therefore, we desire to have our statistical model describing the mountain while discarding the debris. There is no one method giving the “correct” answer. Trying a few values of m is recommended, with the final choice being driven by the subject matter and the interpretability of the solution.

Computation

Most standard statistical software packages have functions or procedures for performing factor analysis. Both the SAS and STATA procedure are called “factor,” while the S-PLUS function is called “factanal.” SPSS can also perform factor analysis via a pull down menu. All packages have the most popular methods for initial estimation and rotations. Each package also has a variety of other techniques available. Estimation of the unobservable factors is often a goal, and can be produced by these software packages.^[13] Once estimated, these factors are often utilized as if they were observed data. However, given that the estimation error is ignored, the results underestimate the true associations.^[14]

CONFIRMATORY FACTOR ANALYSIS

In EFA no prior knowledge about the underlying structure is assumed. That is, the number of factors, m , is unknown. In CFA, the researcher has a preconceived notion of the structure, which is based upon a theoretic framework. This method can also be employed to validate structures previously identified by EFA. Elements of the factor loading matrix are restricted so that factors are associated with specific variables. This approach falls under a broader class of structural equation models.^[15] CFA is often performed using a dedicated software package such as AMOS, EQS,

or LISREL. Alternatively, the factors can be modeled using “proc calis” in SAS.

Once the proposed model is estimated, the goodness-of-fit of the model must be assessed. The first step is generally to check that the model is locally identified, that is, the estimated parameters are of the correct sign and magnitude, variance estimates are positive, and the entries in the residual matrix $S - \hat{\Sigma}$ are uniformly small. Secondly, tests or indices of fit are used to evaluate the overall goodness-of-fit. Over 30 such tests have been proposed.^[16] Owing to their similarity with the R^2 and adjusted R^2 tests in multiple regression, the goodness-of-fit index (GFI) and adjusted GFI are two of the more commonly employed indices. Further, a reasonably fitting model will have a Bentler comparative fit index and a Bentler and Bonett index over 0.9. In practice, more than one test is needed to evaluate the overall fit. Usually, the model does not fit the data. In such cases, the complexity of the proposed model should be reduced, rather than expanded. Likelihood ratio, Lagrange Multiplier, and Wald tests exist to compare nested models.

Extensions

Adoption of factor analytic methods by the medical community has been slow^[17] because they were developed largely for continuous responses. It has been pointed out that ignoring the true distribution of the data and forcing dichotomous or ordinal responses into continuous data models can be problematic.^[18] Extensions of classic factor analytic methods that utilize estimated or polychoric correlations among sets of dichotomous responses or groups of ordered responses have been proposed.^[19] One class of models, Item Response Theory (IRT), was originally developed within the context of educational testing to combine dichotomous measures into a single latent construct. The original form of these IRT models (the Rasch model) utilized a joint logit model to estimate separate difficulty parameters for each item, but assumed a constant association (discrimination parameter) with the latent trait across all items within a domain, allowing for ranking and scaling of items along the range of the latent trait. Extensions to sets of nominal, ordered categorical, or rating scale responses also have been proposed.^[20] When each item is allowed to have a differential association with the latent trait, the discrimination parameters have a similar interpretation to the factor loading parameters in their continuous data counterparts.^[21] Just as with factor analysis, the IRT model evaluates sets of observed outcomes that are all of the same type. Recently, software has been developed allowing the modeling of mixed outcome types.^[22] The MPLUS package can fit EFA models with continuous and ordered categorical data, while the CFA module can handle any combination of continuous, ordered categorical, and count data. This program utilizes a probit distribution for the categorical measurements and, thus, is different from the IRT models.

Although it is easy to conceptualize models for mixed outcome types, estimation via maximum likelihood quickly becomes challenging as this method of estimation requires numerical integration. Bayesian methods provide an alternative to dealing with complex estimation. Bayesian approaches to factor analysis involve specifying a prior distribution for model parameters and then using the data to estimate the posterior distribution.^[8] One advantage of the Bayesian approach is that the choice of appropriate prior distributions will produce valid estimates for all model parameters in contrast to methods such as maximum likelihood.^[23] Given that the posterior density is often not of closed form, numerical methods are required for estimation. Advances in computing power and development of Markov Chain Monte Carlo algorithms have made Bayesian factor analysis models easier to implement in practice and have led to renewed interest in these models. Bayesian methods have been applied to non-linear factor analysis models as well as mixed outcome types and longitudinal data.^[24] The Bayesian framework also allows for a unified procedure of model fitting and selection.^[25] Bayesian factor analysis functions (MCMCfactanal, MCMCordfactanal, MCMCmixfactanal) are available as part of the MCMCpack in R.^[26] The example below compares standard software EFA assuming normality of the observed data to an analysis where the observed form of the data has been properly accounted for.

Example

Our example is an EFA of data from the Interstitial Cystitis Database (ICDB) study where the measured variables are of mixed types (normal, binary, and ordinal).

Interstitial Cystitis (IC) is a chronic syndrome characterized by urinary frequency, urgency, and/or pain in the absence of any identifiable cause. The ICDB cohort study was created to follow the natural history of IC in treated patients.^[27] A secondary goal of the study was to investigate the association of IC symptoms with pathologic bladder features. One-third of the subjects agreed to undergo cystoscopy, hydrodistension, and bladder biopsy at the beginning of the study. Data on bladder biopsies were recorded using a 39-item questionnaire designed to capture a wide range of potential processes affecting the development of IC-related symptoms.^[28] By analyzing the correlation among biopsy features, it is hoped that it will be possible to identify some of the biologic processes contributing to IC and the key features affected by these processes.

For our analysis, we selected a subset of 24 items that had a low percentage of missing data and at least some variability among responses. One continuous variable, 16 binary variables, and 7 ordinal variables constitute these items. Of the 211 subjects who underwent bladder biopsy, 203 had complete data for the selected items and were included in these analyses.

Two factor analyses were performed in MPLUS.^[22] The first assumes that all of the variables are normally

distributed while the second accounts for the fact that the distributions are of different types. Estimation of model parameters was done using the method of unweighted least squares. To determine the number of factors for our model, we created scree plots of the eigenvalues in descending order. In both analyses, a three-factor model was suggested because the slope of the plot was steepest through the third factor (Figs. 1 and 2). Consultation with a pathologist

Fig. 1 Scree plot of eigenvalues for analysis 1, assuming all observed variables are normally distributed

confirmed our choice of the three-factor models as they yielded the most biologically plausible interpretation.

Factor loadings using a PROMAX rotation and groupings of the variables based on their factor loadings are presented in Table 1 (for analysis 1) and Table 2 (for analysis 2). The largest factor loading in absolute value for each variable has been highlighted, indicating the factor to which that variable is most strongly related. Factor 2

Fig. 2 Scree plot of eigenvalues for analysis 2, assuming mixed outcome types (continuous, binary, and ordered categorical)

Table 1 Factor Loadings for Analysis 1, Assuming All Observed Variables Are Normally Distributed

Variable (codes)	Factor 1	Factor 2	Factor 3

Table 3 Correlations among the Factors for Analyses 1 and 2

	Analysis 1		Analysis 2	
	Factor 1	Factor 2	Factor 1	Factor 2
Factor 2	0.021		−0.211	
Factor 3	0.383	−0.331	−0.030	−0.142

is clearly defined in both analyses and is related to items 9a, 9b, 11, 22, and 25, which record the amount of urothelium lost and the capacity for urothelial regeneration. The remaining items are related most strongly to factors 1 and 3, although the grouping of the variables differs somewhat between the two analyses. These factors represent the role of mastocytosis and cellular inflammation in the development of IC. The difference in item grouping also results in a difference in correlation among the factors (Table 3).

As this example illustrates, assuming normality when it is not appropriate can have a substantial effect on the results of the analysis. This is especially true when the categorical items have asymmetric distributions, as is the case here. In general, the factor loadings for analysis 1 are smaller

than those for analysis 2, while the correlations among the factors are larger for analysis 1. This leads to less certainty about variable groupings and less clearly-defined factors.

CONCLUSIONS

Given today's computing capabilities, Spearman's goal of summarizing multiple measures to derive information about latent constructs has become a reality. Even when this is not a primary goal, his method and various extensions are valuable tools for multivariate data reduction. As with any form of research, there is a need to use the principles of sound statistical practice. Issues of validity, reliability, and potential for bias need to be addressed for all proposed constructs and measurement instruments; Streiner and Norman^[29] describe these issues. Factor analytic methods have their foundation in the social sciences, but this broad class of models can be utilized in many different settings. Muthén^[30] discusses links between these models, random effects, and causal models, as well as extensions including latent class and growth curve models.

Abstract

Factorial design theory is emerging as a fast, effective way of accumulating knowledge in most major sciences. This entry gives a brief review of the history of factorial design and some relevant theories developed recently and also touches on applications and clinical trials using the method.

INTRODUCTION

Factorial design theory is emerging as a fast, effective way of accumulating knowledge in most major sciences. It has been widely used in agricultural research, quality improvement, and cost reduction. Recently, we have seen its application growing fast in biology, medical research, and clinical trials. In biological processes, for example, the polymerase chain reaction (PCR) of DNA diagnosis and identification is affected by many factors. In a clinical study, when patients need multiple therapies, such as combinations of several medications, investigators may have to study the toxicity and benefit of different drug combinations.^[1] A factorial design can be a cost-effective way to study multiple factors in a single study.

During the last two decades, new theory and methodology, such as search design, sequential probing design, and orthogonal and optimal parallel flats type designs, have been developed in the field of factorial designs. The advancement in factorial design provides a powerful instrument for researchers to generate, interpret and apply scientific experiments much more effectively. We realize that there is a great need for understanding new theory and implementing new methodology in practical problems. However, many of the new techniques can only be found in statistical literature, and not organized for the comprehension of applied statisticians.

In this entry, the brief review of the history of factorial design and some relevant theories developed recently are given. A series of orthogonal designs, which can only be generated by advanced design theories, are presented for some specified two-factor interactions. In addition, applications of mixed orthogonal designs in the PCR process of DNA identification and drug interactions in clinical trials are discussed in the section of “Orthogonal Designs for 3^m Factorial Experiments.” This work may guide applied statisticians to implement optimal designs for practical problems without going through the lengthy and complex mathematics involved in generating orthogonal designs.

HISTORY

Factorial design theory was first introduced by Fisher^[2] in agricultural applications. Bose^[3] established the mathematical foundation of experimental design theory by applying Galois fields and the associated finite geometries. For a symmetric s^n factorial experiment, Rao^[4] showed how to construct an orthogonal array of strength $2d$ [OA($2d$)] from a single flat design for estimating all effects up to d -factor interactions.

A design is said to be orthogonal if and only if the corresponding information matrix is diagonal. Orthogonal designs are optimal designs with respect to many optimality criteria, such as D -, E -, and A -optimality. Using an orthogonal design, the estimators of effects are uncorrelated and the variances of estimates are minimized. Orthogonal arrays play an important role in optimal designs. If a design is an orthogonal array of strength $2d$, it is an optimal design with respect to general criteria^[5,6] from which all factorial effects up to d -factor interactions can be estimated, with the assumption that other higher-order interactions are zero.

In practice, it is difficult to use orthogonal arrays of strength $2d$ for $d > 2$. The number of treatments in orthogonal arrays of the strength $2d$ increases exponentially when the number of factors increases. For an experiment with a large number of factors, the number of treatments in an orthogonal array is too large. Often it is not practical to collect all data corresponding to the treatments. In addition, it may be unnecessary to estimate all effects up to d -factor interactions. Prior knowledge may indicate that some higher-order interactions can be ignored. Therefore it is desirable to develop orthogonal designs with a small number of treatments in order to estimate a specified set of higher-order interactions (not necessarily all effects up to d -factor interactions).

One effective way to construct factorial designs is to use “parallel flats.” Connor and Young^[7] introduced the class of parallel flats designs (PFD). Srivastava and Throop^[8] showed how to generate an OA($2d$) of PFD. The general

theory of parallel flats designs is further studied in Refs. [9] and [10]. In her dissertation, Li^[11] gave a necessary and sufficient condition to generate an orthogonal parallel-flats type of design for estimating a specified set of s^n factorial effects. Series of orthogonal designs for 2^n experiments were also presented in Ref. [11]. These results were also published in Ref. [12]. Using representations of complex theory in factorial effects, Liao^[13] extended the foregoing work to mixed $2^n \times 3^m$ factorial experiments.

ORTHOGONAL DESIGNS FOR S^m FACTORIAL EXPERIMENTS

Consider an s^m factorial experiment. Let $\underline{Y} = (y_1, y_2, \dots, y_N)'$ be an $(N \times 1)$ vector of observations corresponding to N treatment combinations in a design T of size $(m \times N)$. Consider a linear model

$$E(\underline{Y}) = X\underline{F}, \quad \text{var}(\underline{Y}) = \sigma^2 I_N \quad (1)$$

where $\underline{F}$ is a $(\nu \times 1)$ vector of unknown effect parameters, X is the $(N \times \nu)$ design matrix of rank ν , and I_N is the $(N \times N)$ identity matrix. The elements of $\underline{F}$ form a subset of all factorial effects, assuming other effects not in $\underline{F}$ are zero. The estimate of $\underline{F}$ is given by $\hat{\underline{F}} = (X'X)^{-1}X'\underline{Y}$, and the variance matrix of $\hat{\underline{F}}$ is $\text{var}(\hat{\underline{F}}) = \sigma^2(X'X)^{-1}$. The corresponding information matrix is $M = X'X$. The design T is said to be an orthogonal design if and only if M is diagonal.

Consider the defining vector for any effect in $\underline{F}$. Suppose that $F_1, F_2, \dots, F_m$ are m factors of interest, and each factor takes three levels. A general factorial effect may be denoted as

$$e = F_1^{\varepsilon_1} \dots F_m^{\varepsilon_m} \quad (2)$$

where $\varepsilon_i \in \text{GF}(3)$ ($i = 1, \dots, m$). The vector

$$\underline{e} = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_m)' \quad (3)$$

of size $(m \times 1)$ is called the defining vector of the factorial effect e . The general mean μ will have the defining vector $\underline{0}$.

Consider the parallel-flats type of designs for s^m factorial experiments. Suppose that T_i is an $(m \times s^{m-r})$ matrix, whose columns $\underline{t}$ are the solutions to the linear system

$$A\underline{t} = \underline{c}_i, \quad (i = 1, \dots, f) \quad (4)$$

over $\text{GF}(3)$, where A is an $(r \times m)$ matrix of rank r and $\underline{t}$ and $\underline{c}_i$ are vectors of the sizes $(m \times 1)$ and $(r \times 1)$, respectively. Let T be the collection of all the T_i ; i.e.,

$$T = [T_1 : T_2 : \dots : T_i : \dots : T_f] \quad (5)$$

Notice that T is a matrix of size $(m \times N)$, where $N = fs^{m-r}$. Let

$$A = [B : I_{n-r}] \quad \text{and} \quad C = (\underline{c}_1, \dots, \underline{c}_f) \quad (6)$$

The design T is called a parallel-flats type of design determined by the pair of matrices (A, C) , or given by Eq. 4.

In Ref. [12], a simple necessary and sufficient condition on A and C such that T is an orthogonal design is given for a general s^m factorial experiment, where s is a prime or a power of a prime. Theorem 1 provides a way to construct an orthogonal design with a possibly smaller number of treatments.

Theorem 1. Consider the linear model of Eq. 1.^[12] Let T be determined by (A, C) as in Eqs. 4–6. Then T is an orthogonal design for estimating $\underline{F}$ if and only if the following holds.

1. Let e be any effect in $\underline{F}$ with the defining vector $\underline{e}$, if $\underline{e} = \underline{u}'A$, where the vector $\underline{u}(r \times 1)$ is not zero, then $\underline{u}'C(1 \times f)$ must be an OA(1).
2. Let e_1 and e_2 be any two effects in $\underline{F}$ with the defining vectors $\underline{e}_1$ and $\underline{e}_2$, respectively. If $\underline{e}_1 \neq \beta \underline{e}_2$, and $\underline{e}_1 + \gamma \underline{e}_2 = \underline{u}'A$ over $\text{GF}(3)$, where β and γ are nonzero in $\text{GF}(s)$ and $\underline{u}$ is a nonzero vector of size $(r \times 1)$, then $\underline{u}'C$ must be an OA(1).

Now we apply Theorem 1 to generate orthogonal designs for intermediate two-factor interactions, i.e., a subset of all two-factor interactions. For simplicity, we denote any vector of parameters as follows:

$$\begin{aligned} \underline{F}' &= (\mu, F_1, F_1^2, \dots, F_i, F_i^2, F_i^{\varepsilon_i} F_j^{\varepsilon_j}, \dots) \\ &= (0, 1, 1^2, \dots, i, i^2, i^{\varepsilon_i} j^{\varepsilon_j}, \dots) \end{aligned}$$

For example,

$$\begin{aligned} \underline{F}' &= (\mu, F_1, F_1^2, F_2, F_2^2, F_1 F_2, F_1^2 F_2, F_1 F_2^2, F_1^2 F_2^2) \\ &= (0, 1, 1^2, 2, 2^2, 12, 1^2 2, 12^2, 1^2 2^2) \end{aligned}$$

In “Orthogonal Designs for 2^n Factorial Experiments” and “Orthogonal Designs for 3^m Factorial Experiments,” N is the total number of treatments in a design, n (or m) is the number of factors of interest, and ν is the number of parameters in $\underline{F}$. We assume that n (or m) factors are divided into p subgroups, and each subgroup has m_k ($k = 1, \dots, p$) factors in it. The two-factor interactions are either within or between some of the subgroups. All the designs of the following parallel-flats type satisfy the conditions in Theorem 1.

ORTHOGONAL DESIGNS FOR 2^n FACTORIAL EXPERIMENTS

In this section, we provide a class of examples (from 2^n factorial experiments) to illustrate the foregoing theory on orthogonal designs. Given the theory of the last section for any given situation, it is generally relatively simple to obtain A and C matrices by trial and error. Our illustrations include cases where we wish to estimate the general

mean, the main effects, and some two-factor interactions, assuming the remaining factorial effects are negligible. Our designs are such that they enable us to estimate the required parameters under the given conditions. However, in many cases, they may turn out to be better than what we claim; that is, they may enable us to estimate more parameters or to estimate parameters under less-restrictive conditions. Illustrations for other cases of the 2^n series and for general s series or mixed cases will be given elsewhere.

In practice, we often do not have to estimate all the two-factor interactions. We may be interested only in estimating some specific type of two-factor interactions plus the general mean and all the main effects because the remaining effects may be known to be negligible. We shall refer to this as the case of “intermediate resolution.” For example, it is very common to see that elderly patients and AIDS patients take combination treatments. Suppose that a study patient population takes four active combination treatments and that each active treatment has two dose levels. To study the effect of interactions within the first three active treatments, a 2^4 factorial experiment given in Case I, Example 1, may be considered.

For a 2^n factorial experiment, orthogonal fractional designs can be used to estimate the factorial effects by applying the classical theory of experimental design. However, the number of treatments is a power of 2. When the number of factors n is large, this generally gives a large number of treatments. In practice, an individual experimental treatment could be very expensive. Therefore one tries to minimize the number of treatments required to estimate effects. Theorem 1 provides a way to construct an orthogonal design with a possibly smaller number of treatments. By applying it, a number of orthogonal designs are presented in this section for 2^n factorial series of intermediate resolution, where n is in the practical range. In the following, we discuss the intermediate situation in detail.

Suppose that n factors are divided into p subgroups, where the i th ($i = 1, \dots, p$) subgroup has n_i factors in it. Let p' be the number of subgroups of interest, where $p' = p$ or $p' = p - 1$, according to whether the p th subgroup is ignored or not. In other words, if $p' = p - 1$, the factors in the p th subgroup are not involved in the higher-order-factor interactions. Consider the following three cases:

- The interactions within p' subgroups.
- The interactions that involve factors from different subgroups.
- The interactions that arise within some of the subgroups or between some of the subgroups.

We now present the designs for different cases. For convenience, we list the parameters and symbols:

n = number of factors under consideration
 p = number of subgroups

p' = number of subgroups actually involved in the two-factor interactions

n_i = number of the factors in the i th ($i = 1, \dots, p$) subgroup

ν = number of nonnegligible effects

f = number of flats

N = total number of treatments

Let $\tilde{B} = (\underline{b}'_1, \dots, \underline{b}'_p)$ and $\tilde{C} = (\underline{c}'_1, \dots, \underline{c}'_{p'})$, where $\underline{b}'_k$ ($k = 1, \dots, p$) is the k th row of B in Eq. 6 and $\underline{c}'_k$ ($k = 1, \dots, p'$) is the k th row of C . Here, the $\tilde{B}$ is of size $[r(n-r) \times 1]$ and is a “rolled out” form of B ; similarly, $\tilde{C}$ is $(rf \times 1)$ and is a “rolled out” form of C . We also denote the parameter vector $\underline{F} = (\mu, F_1, \dots, F_p, \dots, F_n, F_1F_2, \dots, F_iF_j)'$ as $\underline{F} = F(0, 1, \dots, i, \dots, n, 1:2, \dots, i:j)$. For example, $\underline{F} = (\mu, F_1, F_2, F_3, F_1F_2, F_1F_3, F_2F_3)'$ as $\underline{F} = F(0, 1, 2, 3, 1:2, 1:3, 2:3)$. Hereafter all the designs presented are determined by pairs (A, C) , where (A, C) satisfy the condition in Theorem 1 and where A and C are defined by the corresponding $\tilde{B}$ and $\tilde{C}$.

Case I: Interactions Within Subgroups

Here the n factors are partitioned into p subgroups, the i th subgroup has n_i factors in it, and the two-factor interactions are within p' subgroups, where $p' = p$ or $p' = p - 1$. In Table 1, we list the parameters n, ν, N, f, p, p' , and $n_1, \dots, n_p$ for each of 21 designs, where the number of factors n is from 4 to 10. The designs in Table 1 utilize a single flat

Table 1 Designs for Interactions Within Subgroups

id	n	ν	N	f	p	p'	$(n_1, \dots, n_p)$
1	4	8	8	1	2	1	(3, 1)
2	5	7	8	1	2	1	(2, 3)
3	6	8	8	1	2	1	(2, 4)
4	6	10	16	1	3	3	(2, 2, 2)
5	6	13	16	1	1	1	(4, 2)
6	6	11	16	1	3	2	(3, 2, 1)
7	7	14	16	1	2	1	(4, 3)
8	7	11	16	1	4	3	(2, 2, 2, 1)
9	7	23	32	1	2	1	(6, 1)
10	8	13	16	1	4	4	(2, 2, 2, 2)
11	8	15	16	1	2	1	(4, 4)
12	8	24	32	1	2	1	(6, 2)
13	8	20	32	1	3	2	(2, 5, 1)
14	9	16	16	1	2	1	(4, 5)
15	9	14	16	1	5	4	(2, 2, 2, 2, 1)
16	9	25	32	1	2	1	(6, 3)
17	9	19	32	1	3	1	(3, 3, 3)
18	10	14	16	1	2	1	(3, 7)
19	10	16	16	1	5	5	(2, 2, 2, 2, 2)
20	10	26	32	1	2	1	(6, 4)
21	10	20	32	1	4	3	(3, 3, 3, 1)

(i.e., C is a vector, say, $\underline{c}$). Without loss of generality, we just take $\underline{c} = \underline{0}$. So in the following, we present only the vector of effects $\underline{F}$, the parameters n, N, ν , and the matrices $\tilde{B}$. The set T of the solutions to the linear system $A\underline{t} = \underline{0}$ is then an orthogonal design for estimating the corresponding vector of effects $\underline{F}$. Next, the 21 designs are presented as Cases 1–21.

1. Consider a 2^4 factorial experimental design (Case 1 in Table 1). We are interested in estimating the general mean, all the main effects, and the two-factor interactions within the subgroup $\{F_1, F_2, F_3\}$. The factor F_4 is not involved in the two-factor interactions. Hence we have $n = 4, \nu = 8, p = 2, p' = 1, (n_1, n_2) = (3, 1)$, which are listed in Table 1. The vector of effects is $\underline{F} = (\mu, F_1, F_2, F_3, F_4, F_1F_2, F_1F_3, F_2F_3)' = F(0, 1, 2, 3, 4, 1\cdot2, 1\cdot3, 2\cdot3)$. The orthogonal design T is the set of solutions to the linear equation $A\underline{t} = \underline{0}$ over $\text{GF}(2)$, with total number of treatments $N = 8$, where $A = (1, 1, 1, 1)$ and $\tilde{B} = (111)$.

Cases 2–21 in Table 1 are similar to the preceding. We list only the vector of effects $\underline{F}$, parameters n, N, ν , and the $\tilde{B}$ vector for each case.

2. $\underline{F} = F(0, 1, \dots, 5, 1\cdot2), n = 5, N = 8, \nu = 7, \tilde{B} = (101, 011)$.
3. $\underline{F} = F(0, 1, \dots, 6, 1\cdot2), n = 6, N = 8, \nu = 8, \tilde{B} = (110, 011, 111)$.
4. $\underline{F} = F(0, 1, \dots, 6, 1\cdot2, 3\cdot4, 5\cdot6), n = 6, N = 16, \nu = 10, \tilde{B} = (0101, 1010)$.
5. $\underline{F} = F(0, 1, \dots, 6, 1\cdot2, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 3\cdot4), n = 6, N = 16, \nu = 13, \tilde{B} = (1110, 0111)$.
6. $\underline{F} = F(0, 1, \dots, 6, 1\cdot2, 1\cdot3, 2\cdot3, 4\cdot5), n = 6, N = 16, \nu = 11, \tilde{B} = (0011, 1101)$.
7. $\underline{F} = F(0, 1, \dots, 7, 1\cdot2, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 3\cdot4), n = 7, N = 16, \nu = 14, \tilde{B} = (0110, 0101, 1111)$.
8. $\underline{F} = F(0, 1, \dots, 7, 1\cdot2, 3\cdot4, 5\cdot6), n = 7, N = 16, \nu = 11, \tilde{B} = (1100, 0011, 0101)$.
9. $\underline{F} = F(0, 1, \dots, 7, 1\cdot2, \dots, 1\cdot6, 2\cdot3, \dots, 2\cdot6, \dots, 5\cdot6), n = 7, N = 32, \nu = 23, \tilde{B} = (11001, 00111)$.
10. $\underline{F} = F(0, 1, \dots, 8, 1\cdot2, 3\cdot4, 5\cdot6, 7\cdot8), n = 8, N = 16, \nu = 13, \tilde{B} = (1100, 0011, 0101, 1011)$.
11. $\underline{F} = F(0, 1, \dots, 8, 1\cdot2, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 3\cdot4), n = 8, N = 16, \nu = 15, \tilde{B} = (1100, 1010, 1001, 0111)$.
12. $\underline{F} = F(0, 1, \dots, 8, 1\cdot2, \dots, 1\cdot6, 2\cdot3, \dots, 2\cdot6, \dots, 5\cdot6), n = 8, N = 32, \nu = 24, \tilde{B} = (11010, 10101, 00011)$.
13. $\underline{F} = F(0, 1, \dots, 8, 1\cdot2, 3\cdot4, \dots, 3\cdot7, 4\cdot5, \dots, 4\cdot7, \dots, 6\cdot7), n = 8, N = 32, \nu = 20, \tilde{B} = (10001, 11100, 00111)$.
14. $\underline{F} = F(0, 1, \dots, 9, 1\cdot2, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 3\cdot4), n = 9, N = 16, \nu = 16, \tilde{B} = (1100, 1010, 1001, 0111, 1111)$.
15. $\underline{F} = F(0, 1, \dots, 9, 1\cdot2, 3\cdot4, 5\cdot6, 7\cdot8), n = 9, N = 16, \nu = 14, \tilde{B} = (1100, 1001, 1101, 0011, 1111)$.
16. $\underline{F} = F(0, 1, \dots, 9, 1\cdot2, \dots, 1\cdot6, 2\cdot3, \dots, 2\cdot6, \dots, 5\cdot6), n = 9, N = 32, \nu = 25, \tilde{B} = (10100, 10010, 10001, 00111)$.
17. $\underline{F} = F(0, 1, \dots, 9, 1\cdot2, 1\cdot3, 2\cdot3, 4\cdot5, 4\cdot6, 5\cdot6, 7\cdot8, 7\cdot9, 8\cdot9), n = 9, N = 32, \nu = 19, \tilde{B} = (10100, 01010, 11001, 10111)$.

18. $\underline{F} = F(0, 1, \dots, 10, 1\cdot2, 1\cdot3, 2\cdot3), n = 10, N = 16, \nu = 14, \tilde{B} = (1100, 1010, 1001, 0111, 1111, 0110)$.
19. $\underline{F} = F(0, 1, \dots, 10, 1\cdot2, 3\cdot4, 5\cdot6, 7\cdot8, 9\cdot10), n = 10, N = 16, \nu = 16, \tilde{B} = (1010, 0101, 0110, 1101, 1001, 1110)$.
20. $\underline{F} = F(0, 1, \dots, 10, 1\cdot2, \dots, 1\cdot6, 2\cdot3, \dots, 2\cdot6, \dots, 5\cdot6), n = 10, N = 32, \nu = 26, \tilde{B} = (01100, 01010, 01001, 11110, 10011)$.
21. $\underline{F} = F(0, 1, \dots, 10, 1\cdot2, 1\cdot3, 2\cdot3, 4\cdot5, 4\cdot6, 5\cdot6, 7\cdot8, 7\cdot9, 8\cdot9), n = 10, N = 32, \nu = 20, \tilde{B} = (11000, 01001, 00111, 00101, 10011)$.

Case II: Interactions Between Subgroups

In this section, we consider designs of intermediate resolution, where the two-factor interactions arise between the subgroups. In Table 2, 35 such cases are listed; the parameters n, ν, N, f, p, p' , and $n_1, \dots, n_p$ are also given for each case.

The first 12 designs are given by a single flat. We select $\underline{c} = \underline{0}$. Next, we present the vector of effects $\underline{F}$, the parameters n, N, ν , and the $\tilde{B}$ matrix for each case.

1. $\underline{F} = F(0, 1, 2, 3, 4, 1\cdot2, 1\cdot3), n = 4, N = 8, \nu = 7, \tilde{B} = (111)$.
2. $\underline{F} = F(0, 1, \dots, 5, 1\cdot2, 1\cdot3), n = 5, N = 8, \nu = 8, \tilde{B} = (110, 011)$.
3. $\underline{F} = F(0, 1, \dots, 6, 1\cdot4, 1\cdot5, 1\cdot6, 2\cdot4, 2\cdot5, 2\cdot6, 3\cdot4, 3\cdot5, 3\cdot6), n = 6, N = 16, \nu = 16, \tilde{B} = (1111, 0111)$.
4. $\underline{F} = F(0, 1, \dots, 6, 1\cdot2, \dots, 1\cdot6), n = 6, N = 16, \nu = 12, \tilde{B} = (1110, 0011)$.
5. $\underline{F} = F(0, 1, \dots, 7, 1\cdot2, \dots, 1\cdot7), n = 7, N = 16, \nu = 14, \tilde{B} = (1110, 0101, 0011)$.
6. $\underline{F} = F(0, 1, \dots, 7, 1\cdot4, 1\cdot5, 1\cdot6, 1\cdot7, 2\cdot4, 2\cdot5, 2\cdot6, 2\cdot7, 3\cdot4, 3\cdot5, 3\cdot6, 3\cdot7), n = 7, N = 32, \nu = 23, \tilde{B} = (01111, 11111)$.
7. $\underline{F} = F(0, 1, \dots, 8, 1\cdot2, 1\cdot3, \dots, 1\cdot8), n = 8, N = 16, \nu = 16, \tilde{B} = (0111, 1010, 1001, 1011)$.
8. $\underline{F} = F(0, 1, \dots, 8, 1\cdot6, 1\cdot7, 1\cdot8, 2\cdot6, 2\cdot7, 2\cdot8, 3\cdot6, 3\cdot7, 3\cdot8, 4\cdot6, 4\cdot7, 4\cdot8, 5\cdot6, 5\cdot7, 5\cdot8), n = 8, N = 16, \nu = 16, \tilde{B} = (11000, 01111, 1111)$.

The following orthogonal designs of parallel-flats type consist of more than one flat.

9. Consider a 2^6 factorial experiment. We are interested in estimating the general mean, all the main effects, and the two-factor interactions between the subgroup $\{F_1, F_2, F_3\}$ and the subgroup $\{F_4, F_5\}$. The factor F_6 is not involved into the two-factor interactions. So we have $n = 6, p = 3, p' = 2, \nu = 13, (n_1, n_2, n_3) = (3, 2, 1)$, which are listed in Table 2, Case 9. The vector of effects is $\underline{F} = F(0, 1, \dots, 6, 1\cdot4, 1\cdot5, 2\cdot4, 2\cdot5, 3\cdot4, 3\cdot5)$. The orthogonal design with total number of treatments $N = 16$ is determined by (A, C) , where

Table 2 Designs for Interactions Between Subgroups

id	n	ν	N	f	p	p'	$(n_1, \dots, n_p)$
1	4	8	8	1	2	2	(1, 3)

35	26	74	96	24	4	3	(1, 1, 23, 1)

$$A = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix}$$

and

$$C = \begin{pmatrix} 1 & 0 & 1 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 1 \end{pmatrix}$$

For simplicity, we say that A and C are given by $\tilde{B} = (00, 00, 00, 11)$ and $\tilde{C} = (1010, 1100, 1001, 0111)$, respectively.

In the following, the C matrices are obtained from the (12×12) Hadamard matrix

$$H_{12 \times 12} = \begin{bmatrix} + & + & + & + & + & + & + & + & + & + & + & + \\ + & - & - & + & - & - & - & + & + & + & - & + \\ + & - & + & - & - & - & + & + & + & - & + & - \\ + & + & - & - & - & + & + & + & - & + & - & - \\ + & - & - & - & + & + & + & - & + & - & - & + \\ + & - & - & + & + & + & - & + & - & - & + & - \\ + & - & + & + & + & - & + & - & - & + & - & - \\ + & + & + & + & - & + & - & - & + & - & - & - \\ + & + & + & - & + & - & - & + & - & - & - & + \\ + & + & - & + & - & - & + & - & - & + & + & + \\ + & - & + & - & - & + & - & - & - & + & + & + \\ + & + & - & - & + & - & - & - & + & + & + & - \end{bmatrix}$$

Here $+$ and $-$ represent $+1$ and -1 , respectively. Let $\tilde{H}_{12 \times 12}$ be the matrix obtained from $H_{12 \times 12}$ by changing all -1 's into 0 's, and $\tilde{H}_{11 \times 12}$ be the matrix obtained by deleting the first row of $\tilde{H}_{12 \times 12}$. It is known that $\tilde{H}_{11 \times 12}$ and $\tilde{H}_{k \times 12}$ are $OA(2)$, where $\tilde{H}_{k \times 12}$ is the matrix with any k rows ($k \leq 11$) of $\tilde{H}_{11 \times 12}$. In the following eight cases, we select C as the matrices $\tilde{H}_{k \times 12}$.

- $\underline{F} = F(0, \dots, 9, 1-2, 1-3, \dots, 1-9)$, $n = 9$, $N = 24$, $\nu = 18$, $\tilde{B} = (1, 0, 0, 0, 0, 0, 0, 0, 0)$, $C = \tilde{H}_{8 \times 12}$.
- $\underline{F} = F(0, \dots, 10, 1-2, \dots, 1-10)$, $n = 10$, $N = 24$, $\nu = 20$, $\tilde{B} = (1, 0, 0, 0, 0, 0, 0, 0, 0, 0)$, and $C = \tilde{H}_{9 \times 12}$.
- $\underline{F} = F(0, 1, \dots, 11, 1-2, 1-3, \dots, 1-11)$, $n = 10$, $N = 24$, $\nu = 22$, $\tilde{B} = (1, 0, 0, 0, 0, 0, 0, 0, 0, 0)$, and $C = \tilde{H}_{10 \times 12}$.
- $\underline{F} = F(0, 1, \dots, 11, 1-2, 1-3, \dots, 1-11, 2-3, \dots, 2-11)$, $n = 11$, $N = 48$, $\nu = 31$, $\tilde{B} = (10, 01, 00, 00, 00, 00, 00, 00, 00, 00)$, and $C = \tilde{H}_{9 \times 12}$.
- $\underline{F} = F(0, 1, \dots, 12, 1-2, 1-3, \dots, 1-12)$, $n = 12$, $N = 24$, $\nu = 24$, $\tilde{B} = (1, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0)$, and $C = \tilde{H}_{11 \times 12}$.
- $\underline{F} = F(0, 1, \dots, 12, 1-2, 1-3, \dots, 1-12, 2-3, \dots, 2-12)$, $n = 12$, $N = 48$, $\nu = 34$, $\tilde{B} = (10, 01, 00, 00, 00, 00, 00, 00, 00, 00, 00)$, and $C = \tilde{H}_{10 \times 12}$.
- $\underline{F} = F(0, 1, \dots, 13, 1-2, 1-3, \dots, 1-13, 2-3, \dots, 2-13)$, $n = 13$, $N = 48$, $\nu = 37$, $\tilde{B} = (10, 01, 00, 00, 00, 00, 00, 00, 00, 00, 00, 00)$, and $C = \tilde{H}_{11 \times 12}$.
- $\underline{F} = F(0, 1, \dots, 14, 1-2, 1-3, \dots, 1-13, 2-3, \dots, 2-13)$, $n = 14$, $N = 48$, $\nu = 38$, $\tilde{B} = (10, 01, 00, \dots, 00, 11)$. Here C is derived from $\tilde{H}_{12 \times 12}$ by exchanging the positions of the first row and the last row of $\tilde{H}_{12 \times 12}$.

In the following, we use the (20×20) Hadamard matrix (see Equation on next page) to select the C matrices. Let $\tilde{H}_{20 \times 20}$ be the matrix obtained from $\tilde{H}_{19 \times 20}$ by changing -1 's into 0 's, and $\tilde{H}_{19 \times 20}$ be the matrix obtained by deleting the first row of $\tilde{H}_{20 \times 20}$. It is known that $\tilde{H}_{19 \times 20}$ and $\tilde{H}_{k \times 20}$ are $OA(2)$, where $\tilde{H}_{k \times 20}$ is the matrix with any k rows ($k \leq 19$) of $\tilde{H}_{19 \times 20}$. In the following cases, we select C as the matrices $\tilde{H}_{k \times 20}$.

30. $\underline{F} = F(0, 1, \dots, 23, 1\cdot2, 1\cdot3, \dots, 1\cdot23), n = 23, N = 48, \nu = 46, \tilde{B} = (1, 0, \dots, 0),$ and $C = \tilde{H}_{22 \times 24}.$
31. $\underline{F} = F(0, 1, \dots, 23, 1\cdot2, 1\cdot3, \dots, 1\cdot23, 2\cdot3, \dots, 2\cdot23), n = 23, N = 96, \nu = 67, \tilde{B} = (10, 01, \dots, 00),$ and $C = \tilde{H}_{21 \times 24}.$
32. $\underline{F} = F(0, 1, \dots, 24, 1\cdot2, 1\cdot3, \dots, 1\cdot24), n = 24, N = 48, \nu = 48, \tilde{B} = (1, 0, \dots, 0),$ and $C = \tilde{H}_{23 \times 24}.$
33. $\underline{F} = F(0, 1, \dots, 24, 1\cdot2, 1\cdot3, \dots, 1\cdot24, 2\cdot3, \dots, 2\cdot24), n = 24, N = 96, \nu = 70, \tilde{B} = (10, 01, \dots, 00),$ and $C = \tilde{H}_{22 \times 24}.$
34. $\underline{F} = F(0, 1, \dots, 25, 1\cdot2, 1\cdot3, \dots, 1\cdot25, 2\cdot3, \dots, 2\cdot25), n = 25, N = 96, \nu = 73, \tilde{B} = (10, 01, 00, \dots, 00),$ and $C = \tilde{H}_{23 \times 24}.$
35. $\underline{F} = F(0, 1, \dots, 26, 1\cdot2, 1\cdot3, \dots, 1\cdot25, 2\cdot3, \dots, 2\cdot25), n = 26, N = 96, \nu = 74, \tilde{B} = (10, 01, 00, \dots, 00, 11),$ and $C(24 \times 24)$ is obtained by exchanging the first row and the last row of $\tilde{H}_{24 \times 24}.$

Case III: Interactions Between and Within Subgroups

Consider the situations where the two-factor interactions occur either within subgroups or between subgroups. In Table 3, we list eight such examples. Here all the factors are divided into three or four subgroups. The two-factor interactions are between the first two subgroups and within the third subgroup. The fourth subgroup (if it exists) is not involved in the two-factor interactions. Since the designs in Table 3 consist of a single flat, i.e., $C = c = 0$, we give the vector of effects $\underline{F}$, parameters n, N, ν , and the corresponding $\tilde{B}$ matrix for each case.

1. $\underline{F} = F(0, 1, \dots, 6, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 5\cdot6), n = 6, N = 16, \nu = 12, \tilde{B} = (1110, 1101).$
2. $\underline{F} = F(0, 1, \dots, 7, 1\cdot2, 1\cdot3, 1\cdot4, 5\cdot6, 5\cdot7, 6\cdot7), n = 7, N = 16, \nu = 14, \tilde{B} = (0111, 1100, 1001).$
3. $\underline{F} = F(0, 1, \dots, 7, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 5\cdot6), n = 7, N = 16, \nu = 13, \tilde{B} = (0101, 0011, 1001).$
4. $\underline{F} = F(0, 1, \dots, 8, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 5\cdot6), n = 8, N = 16, \nu = 14, \tilde{B} = (0101, 0011, 1010, 1110).$
5. $\underline{F} = F(0, 1, \dots, 8, 1\cdot4, 1\cdot5, 1\cdot6, 2\cdot4, 2\cdot5, 2\cdot6, 3\cdot4, 3\cdot5, 3\cdot6, 7\cdot8), n = 8, N = 32, \nu = 19, \tilde{B} = (11100, 01110, 11101).$
6. $\underline{F} = F(0, 1, \dots, 9, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 5\cdot6), n = 9, N = 16, \nu = 15, \tilde{B} = (11100, 01110, 10001, 00111).$
7. $\underline{F} = F(0, 1, \dots, 9, 1\cdot4, 1\cdot5, 1\cdot6, 2\cdot4, 2\cdot5, 2\cdot6, 3\cdot4, 3\cdot5, 3\cdot6, 7\cdot8, 7\cdot9, 8\cdot9), n = 9, N = 32, \nu = 22, \tilde{B} = (11100, 00111, 11010, 10001).$

Table 3 Designs for Interactions Within and Between Subgroups

id	n	ν	N	f	p	p'	$(n_1, \dots, n_p)$
1	6	12	16	1	3	3	(2, 2, 2)
2	7	14	16	1	3	3	(1, 3, 3)
3	7	13	16	1	4	3	(2, 2, 2, 1)
4	8	14	16	1	4	3	(2, 2, 2, 2)
5	8	19	32	1	3	3	(3, 3, 2)
6	9	15	16	1	4	3	(2, 2, 2, 3)
7	9	22	32	1	3	3	(3, 3, 3)
8	10	16	16	1	4	3	(2, 2, 2, 4)

8. $\underline{F} = F(0, 1, \dots, 10, 1\cdot3, 1\cdot4, 2\cdot3, 2\cdot4, 5\cdot6), n = 10, N = 16, \nu = 16, \tilde{B} = (11000, 10100, 10010, 10001, 00111).$

ORTHOGONAL DESIGNS FOR 3^m FACTORIAL EXPERIMENTS

In the following examples, N is the total number of treatments in a design, m is the number of factors of interest, and ν is the number of parameters in F . We assume that m factors are divided into p subgroups, and each subgroup has m_k ($k = 1, \dots, p$) factors in it. The two-factor interactions are either within or between some of the subgroups. All of the following designs of parallel-flats type satisfy the conditions in Theorem 1.

Case 1. Consider a 3^4 factorial experiment. The factorial effects given in the vector

$$\begin{aligned} \underline{F} = & (\mu, F_1, F_2, F_3, F_4, F_1^2, F_2^2, F_3^2, F_4^2, F_1F_2, F_1F_3, F_2F_3, F_1F_2^2, F_1F_3^2, \\ & F_2F_3^2, F_1^2F_2, F_1^2F_3, F_2^2F_3, F_1^2F_2^2, F_1^2F_3^2, F_2^2F_3^2) \\ = & (0, 1, 2, 3, 4, 1^2, 2^2, 3^2, 4^2, 12, 13, 23, 12^2, 13^2, 23^2, 1^22, 1^23, \\ & 2^23, 1^22^2, 1^23^2, 2^23^2) \end{aligned}$$

have the property that the two-factor interactions occur within the subgroup $\{1, 2, 3\}$. Consider the design T given by the linear equation

$$A\underline{t} = t_1 + t_2 + t_3 + t_4 = C$$

over $\text{GF}(3)$, where $A = (1 \ 1 \ 1 \ 1)$, and $C = 0$. By Theorem 1, the design (see Equation below) is an orthogonal design for estimating $\underline{F}$. Here $m = 4, \nu = 21, p = 2, m_1 = 3, m_2 = 1, N = 27$.

In the following examples of orthogonal designs, we only give matrices A, C , and $\underline{F}$.

$$T = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 \\ 0 & 0 & 0 & 1 & 1 & 1 & 2 & 2 & 2 & 0 & 0 & 0 & 1 & 1 & 1 & 2 & 2 & 0 & 0 & 0 & 1 & 1 & 1 & 2 & 2 & 2 \\ 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 \\ 0 & 2 & 1 & 2 & 1 & 0 & 1 & 0 & 2 & 2 & 1 & 0 & 1 & 0 & 2 & 0 & 2 & 1 & 1 & 0 & 2 & 0 & 2 & 1 & 2 & 1 & 0 \end{pmatrix}$$

Case 2. Consider a 3^5 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 5, 1^2, \dots, 5^2, 12, 13, 23, 12^2, 13^2, 23^2, 1^2 2, 1^2 3, 2^2 3, 1^2 2^2, 1^2 3^2, 2^2 3^2)$$

are such that the two-factor interactions occur within the subgroup $\{1, 2, 3\}$. The design T given by $A_t = C$, where

$$A = \begin{pmatrix} 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 1 \end{pmatrix}, \quad C = \underline{0}$$

is an orthogonal design for estimating F . Here $m = 5$, $\nu = 23$, $p = 2$, $m_1 = 3$, $m_2 = 2$, $N = 27$.

Case 3. Consider a 3^6 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 6, 1^2, \dots, 6^2, 12, 13, 23, 12^2, 13^2, 23^2, 1^2 2, 1^2 3, 2^2 3, 1^2 2^2, 1^2 3^2, 2^2 3^2)$$

are such that the two-factor interactions occur within the subgroup $\{1, 2, 3\}$. The orthogonal design T given by $A_t = \underline{0}$, where

$$A = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 \end{pmatrix}, \quad C = \underline{0}$$

is an orthogonal design for estimating F . Here $m = 6$, $\nu = 25$, $p = 2$, $m_1 = 3$, $m_2 = 3$, $N = 27$.

In the following examples, the two-factor interactions occur between subgroups.

Case 4. Consider a 3^4 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, 2, 3, 4, 1^2, 2^2, 3^2, 4^2, 14, 24, 34, 14^2, 24^2, 34^2, 1^2 4, 2^2 4, 3^2 4, 1^2 4^2, 2^2 4^2, 3^2 4^2)$$

are such that the two-factor interactions are between the subgroups $\{1, 2, 3\}$ and $\{4\}$. By Theorem 1, the design T given by the solution to the linear equation $A_t = t_1 + t_2 + t_3 + t_4 = C$, where $A = (1 \ 1 \ 1 \ 1)$ and $C = \underline{0}$, is an orthogonal design for estimating $\underline{F}$. Here $m = 4$, $\nu = 21$, $p = 2$, $m_1 = 3$, $m_2 = 1$, $N = 27$.

Case 5. Consider a 3^5 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 5, 1^2, \dots, 5^2, 15, 25, 35, 45, 15^2, 25^2, 35^2, 45^2, 1^2 5, 2^2 5, 3^2 5, 4^2 5, 1^2 5^2, 2^2 5^2, 3^2 5^2, 4^2 5^2)$$

are such that the two-factor interactions are between the subgroups $\{1, 2, 3, 4\}$ and $\{5\}$. The design T given by $A_t = C$ is an orthogonal design for estimating $\underline{F}$, where

$$A = \begin{pmatrix} 1 & 1 & 1 & 1 & 0 \\ 0 & 1 & 1 & 1 & 1 \end{pmatrix}, \quad C = \underline{0}$$

Here $m = 5$, $\nu = 27$, $p = 2$, $m_1 = 4$, $m_2 = 1$, $N = 27$. The number of the parameters in $\underline{F}$ is equal to the number of treatments in T . The orthogonal design T is a saturated orthogonal design.

Case 6. Consider a 3^6 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 6, 1^2, \dots, 6^2, 14, 24, 34, 14^2, 24^2, 34^2, 1^2 4, 2^2 4, 3^2 4, 1^2 4^2, 2^2 4^2, 3^2 4^2)$$

are such that the two-factor interactions are between the subgroups $\{1, 2, 3\}$ and $\{4\}$. The subgroup $\{5, 6\}$ is not involved in the two-factor interactions. By Theorem 1, the design T given by $A_t = C$ is an orthogonal design for estimating $\underline{F}$, where

$$A = \begin{pmatrix} 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 \end{pmatrix}, \quad C = \underline{0}$$

Here $m = 6$, $\nu = 25$, $p = 3$, $m_1 = 3$, $m_2 = 1$, $m_3 = 2$, $N = 27$.

Case 7. Consider a 3^7 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 7, 1^2, \dots, 7^2, 14, 24, 34, 14^2, 24^2, 34^2, 1^2 4, 2^2 4, 3^2 4, 1^2 4^2, 2^2 4^2, 3^2 4^2)$$

are such that the two-factor interactions are between the subgroups $\{1, 2, 3\}$ and $\{4\}$. The subgroup $\{5, 6, 7\}$ is not involved in the two-factor interactions. The design T given by $A_t = C$ is an orthogonal design for estimating $\underline{F}$, where

$$A = \begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix}, \quad C = \underline{0}$$

Here $m = 7$, $\nu = 25$, $p = 3$, $m_1 = 3$, $m_2 = 1$, $m_3 = 3$, $N = 27$.

Bose and Bush^[14] gave an orthogonal array $H(7 \times 18)$ of strength 2 as follows:

$$H = \begin{pmatrix} 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 & 0 & 1 & 2 \\ 0 & 1 & 2 & 0 & 1 & 2 & 1 & 2 & 0 & 2 & 0 & 1 & 1 & 2 & 0 & 2 & 0 & 1 \\ 0 & 1 & 2 & 1 & 2 & 0 & 0 & 1 & 2 & 2 & 0 & 1 & 2 & 0 & 1 & 1 & 2 & 0 \\ 0 & 1 & 2 & 2 & 0 & 1 & 2 & 0 & 1 & 0 & 1 & 2 & 1 & 2 & 0 & 1 & 2 & 0 \\ 0 & 1 & 2 & 1 & 2 & 0 & 2 & 0 & 1 & 1 & 2 & 0 & 0 & 1 & 2 & 2 & 0 & 1 \\ 0 & 1 & 2 & 2 & 0 & 1 & 1 & 2 & 0 & 1 & 2 & 0 & 2 & 0 & 1 & 0 & 1 & 2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 1 & 2 \end{pmatrix} \quad (7)$$

Notice that any submatrix $\hat{H}(2 \times 18)$ of H is OA(2). Therefore a linear combination of any two rows of H over GF(3) is an OA(1). Now we use the matrix H to construct orthogonal designs.

Case 8. Consider a 3^4 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, 2, 3, 4, 1^2, 2^2, 3^2, 4^2, 12, 13, 23, 12^2, 13^2, 23^2, 1^2 2, 1^2 3, 2^2 3, 1^2 2^2, 1^2 3^2, 2^2 3^2)$$

are such that the two-factor interactions occur within the subgroup $\{1, 2, 3\}$. An orthogonal design for estimating $\underline{F}$ is given by $A_t = C_{3 \times 18}$, where

$$A = \begin{pmatrix} 1 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

and $C_{3 \times 18}$ consists of the first three rows of H in Eq. 7. Here $m = 4$, $\nu = 21$, $p = 2$, $m_1 = 3$, $m_2 = 1$, $N = 3 \times 18 = 54$.

Case 9. Consider a 3^5 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 5, 1^2, \dots, 5^2, 15, \dots, 45, 15^2, \dots, 45^2, 1^2 5, \dots, 4^2 5, 1^2 5^2, \dots, 4^2 5^2)$$

are such that the two-factor interactions occur between the subgroups $\{1, 2, 3, 4\}$ and $\{5\}$. An orthogonal design for estimating $\underline{F}$ is given by $A_t = C_{4 \times 18}$, where

$$A = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 \end{pmatrix}$$

and $C_{4 \times 18}$ consists of the first four rows of H in Eq. 7. Here $m = 5$, $\nu = 27$, $p = 2$, $m_1 = 4$, $m_2 = 1$, $N = 3 \times 18 = 54$.

Case 10. Consider a 3^6 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 6, 1^2, \dots, 6^2, 16, \dots, 56, 16^2, \dots, 56^2, 1^2 6, \dots, 5^2 6, 1^2 6^2, \dots, 5^2 6^2)$$

are such that the two-factor interactions occur between the subgroups $\{1, 2, 3, 4, 5\}$ and $\{6\}$. An orthogonal design for estimating $\underline{F}$ is given by $A_t = C_{5 \times 18}$, where

$$A = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix}$$

and $C_{5 \times 18}$ consists of the first five rows of H in Eq. 7. Here $m = 6$, $\nu = 33$, $p = 2$, $m_1 = 5$, $m_2 = 1$, $N = 3 \times 18 = 54$.

Case 11. Consider a 3^7 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 7, 1^2, \dots, 7^2, 17, \dots, 67, 17^2, \dots, 67^2, 1^2 7, \dots, 6^2 7, 1^2 7^2, \dots, 6^2 7^2)$$

have the property that the two-factor interactions occur between the subgroups $\{1, \dots, 6\}$ and $\{7\}$. An orthogonal design for estimating $\underline{F}$ is given by $A_t = C_{6 \times 18}$, where

$$A = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix}$$

and $C_{6 \times 18}$ consists of the first six rows of H in Eq. 7. Here $m = 7$, $\nu = 39$, $p = 2$, $m_1 = 6$, $m_2 = 1$, $N = 3 \times 18 = 54$.

Case 12. Consider a 3^8 factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 8, 1^2, \dots, 8^2, 18, \dots, 78, 18^2, \dots, 78^2, 1^2 8, \dots, 7^2 8, 1^2 8^2, \dots, 7^2 8^2)$$

have the property that the two-factor interactions occur between the subgroups $\{1, \dots, 7\}$ and $\{8\}$. An orthogonal design for estimating $\underline{F}$ is given by $A_t = C_{7 \times 18}$, where

$$A = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix}$$

and $C_{7 \times 18} = H$ given by Eq. 7. Here $m = 8$, $\nu = 45$, $p = 2$, $m_1 = 7$, $m_2 = 1$, $N = 3 \times 18 = 54$.

ORTHOGONAL DESIGNS FOR MIXED $2^n \times 3^m$ FACTORIAL EXPERIMENTS

The mixed $2^n \times 3^m$ factorial experiments are very common in practice. It is useful to be able to generate an orthogonal design to estimate any specified set of mixed factorial effects. Consider the parallel-flats type of designs for the mixed factorial experiment. Let T_{li} be the set of solutions to the linear system

$$A_1 t_1 = c_{1i}, \quad (i = 1, 2, \dots, f) \quad (8)$$

over GF(2). Let T_{2i} be the set of solutions to the linear system

$$A_2 t_2 = c_{2i}, \quad (i = 1, 2, \dots, f) \quad (9)$$

over GF(3). The PFD design T for $2^n \times 3^m$ with $N = f \times 2^{n-r_1} \times 3^{m-r_2}$ treatments is defined as follows:

$$T = T_{11} \otimes_f T_{21} + \dots + T_{1f} \otimes_f T_{2f} \quad (10)$$

where $\otimes_f$ is the product defined in Ref. [7], and shown as in Cases 1–4 of this section.

The extension of Theorem 1 to the mixed case was given in Ref. [13]. Now we review the results. First consider the following definition.

Definition 1. Let Q be a $2 \times f$ array whose first row has the elements from the set $\{0, 1\}$, and whose second row has the elements from the set $\{0, 1, 2\}$. Let k_{ij} be the number of column vectors $(i, j)'$ of Q ($i = 0, 1; j = 0, 1, 2$).

1. Q is said to have the property O_1 if $k_{00} - k_{10} = k_{01} - k_{11} = k_{02} - k_{12}$.
2. Q is said to have property Q_2 if $k_{00} = k_{10}, k_{01} = k_{11}$ and $k_{02} = k_{12}$.
3. Q is said to have property O_3 if $k_{00} = k_{01} = k_{02}$ and $k_{10} = k_{11} = k_{12}$.
4. Q is said to have property O_4 if $k_{00} = k_{01} = k_{02} = k_{10} = k_{11} = k_{12}$, i.e., Q is an $OA(2)$.

Notice that the model of Eq. 1 and the defining vectors can easily be extended to the mixed $2^n \times 3^m$ factorial experiment. We use the same notation as in “Orthogonal Designs for s^m Factorial Experiments” for the mixed experiments.

Let $\underline{F}$ be a set of factorial effects in a $2^n \times 3^m$ experiment. Suppose that e_1 and e_2 are any effects in $\underline{F}$, and $\underline{e}_1$ and $\underline{e}_2$ are the corresponding defining vectors. Let $\underline{e}'_1 = (\underline{e}'_{11}, \underline{e}'_{21})$ and $\underline{e}'_2 = (\underline{e}'_{12}, \underline{e}'_{22})$, where $\underline{e}'_{11}(1 \times n)$ and $\underline{e}_{12}(1 \times n)$ are over $GF(2)$, $\underline{e}'_{21}(1 \times m)$ and $\underline{e}_{22}(1 \times m)$ are over $GF(3)$. Then we define the operation $\oplus$ as

$$\underline{e} \oplus \gamma \underline{e}_2 = (\underline{e}_{11} + \gamma \underline{e}_{12}, \underline{e}_{21} + \gamma \underline{e}_{22})$$

Define

$$\underline{F}^2 = \{\underline{e}_1 \oplus \gamma \underline{e}_2 \mid \text{for } e_1, e_2 \in \underline{F}, \gamma = 1, 2\}$$

Theorem 2. In a $2^n \times 3^m$ experiment, let design T be described as in Eq. 10, and let M be the information matrix for estimating $\underline{F}$ by using $T^{[13]}$. Then T is orthogonal if and only if the following conditions hold.

1. For $(\underline{e}_1, \underline{0}) \in \underline{F}^2$, if there exists a nonzero vector $\underline{u}'_1(1 \times r_1)$ over $GF(2)$ such that $\underline{e}_1 = \underline{u}'_1 A_1$, then $\underline{u}'_1 C_1$ must be an $OA(1)$, where $C_1 = (\underline{c}_{11}, \underline{c}_{12}, \dots, \underline{c}_{1f})$.
2. For $(\underline{0}, \underline{e}_2) \in \underline{F}^2$, if there exists a nonzero vector $\underline{u}'_2(1 \times r_2)$ over $GF(3)$ such that $\underline{e}_2 = \underline{u}'_2 A_2$, then $\underline{u}'_2 C_2$ must be an $OA(1)$, where $C_2 = (\underline{c}_{21}, \underline{c}_{22}, \dots, \underline{c}_{2f})$.
3. Suppose $(\underline{e}_1, \underline{e}_2) \in \underline{F}^2$, but $(\underline{e}_1, \underline{0}), (\underline{0}, \underline{e}_2) \notin \underline{F}^2$. If there exist a nonzero vector $\underline{u}'_1(1 \times r_1)$ over $GF(2)$ and a nonzero vector $\underline{u}'_2(1 \times r_2)$ over $GF(3)$ such that $\underline{e}_1 = \underline{u}'_1 A_1$ and $\underline{e}_2 = \underline{u}'_2 A_2$, then the matrix

$$\begin{bmatrix} \underline{u}'_1 & C_1 \\ \underline{u}'_2 & C_2 \end{bmatrix}$$

must have property O_1 .

4. Suppose $(\underline{e}'_1, \underline{e}_2), (\underline{e}_1, \underline{0}) \in \underline{F}^2$, but $(\underline{0}, \underline{e}_2) \notin \underline{F}^2$. If there exist a nonzero vector $\underline{u}'_1(1 \times r_1)$ over $GF(2)$ and a nonzero vector $\underline{u}'_2(1 \times r_2)$ over $GF(3)$ such that $\underline{e}_1 = \underline{u}'_1 A_1$ and $\underline{e}_2 = \underline{u}'_2 A_2$, then

$$\begin{bmatrix} \underline{u}'_1 & C_1 \\ \underline{u}'_2 & C_2 \end{bmatrix}$$

must have property O_2 .

5. Suppose $(\underline{e}_1, \underline{e}_2), (\underline{0}, \underline{e}_2) \in \underline{F}^2$, but $(\underline{e}_1, \underline{0}) \notin \underline{F}^2$. If there exist a nonzero vector $\underline{u}'_1(1 \times r_1)$ over $GF(2)$ and a nonzero vector $\underline{u}'_2(1 \times r_2)$ over $GF(3)$ such that $\underline{e}_1 = \underline{u}'_1 A_1$ and $\underline{e}_2 = \underline{u}'_2 A_2$, then

$$\begin{bmatrix} \underline{u}'_1 & C_1 \\ \underline{u}'_2 & C_2 \end{bmatrix}$$

must have property O_3 .

6. Suppose $(\underline{e}_1, \underline{e}_2), (\underline{e}_1, \underline{0}), (\underline{0}, \underline{e}_2) \in \underline{F}^2$. If there exist a nonzero vector $\underline{u}'_1(1 \times r_1)$ over $GF(2)$ and a nonzero vector $\underline{u}'_2(1 \times r_2)$ over $GF(3)$ such that $\underline{e}_1 = \underline{u}'_1 A_1$ and $\underline{e}_2 = \underline{u}'_2 A_2$, then

$$\begin{bmatrix} \underline{u}'_1 & C_1 \\ \underline{u}'_2 & C_2 \end{bmatrix}$$

must have property O_4 .

Now we apply Theorem 2 to generate the mixed factorial experiments.

Case 1. Consider a $2^3 \times 3$ factorial experiment. There are four factors F_1, F_2, F_3 , and F_4 , where F_1, F_2 , and F_3 take two levels $\{0, 1\}$ and F_4 takes three levels $\{0, 1, 2\}$. The factorial effects of interest are given in the vector

$$\begin{aligned} \underline{F}' &= (\mu, F_1, F_2, F_3, F_4, F_1 F_2, F_1 F_3, F_1 F_4, F_2 F_3, F_2 F_4, F_3 F_4, F_1 F_2 F_3, F_1 F_2 F_4, F_1 F_3 F_4, F_2 F_3 F_4) \\ &= (0, 1, 2, 3, 4, 4^2, 14, 24, 34, 14^2, 24^2, 34^2) \end{aligned}$$

The two-factor interactions in $\underline{F}$ are between the subgroups $\{1, 2, 3\}$ and $\{4\}$. Let $T_1 = [T_{11}, T_{12}, T_{13}]$, and T_{1i} ($i = 1, 2, 3$) with size (3×4) be the solutions to the linear $A_1 t_1 = \underline{c}_{1i}$, where $t_1' = (t_1, t_2, t_3)$, $A_1 = (111)$, and $\underline{c}_{1i} = 0$. Let $T_2 = [T_{21}, T_{22}, T_{23}]$ and let T_{2i} ($i = 1, 2, 3$) with size (1×3) be the solutions to the linear $A_2 t_2 = \underline{c}_{2i}$, where $t_2' = (t_4)$, $A_2 = (1)$, and $\underline{c}_{2i} = 0$. Here $n = 3, m = 1, f = 3$. Clearly T_1 and T_2 are orthogonal designs for estimating the main effects of a 2^3 and a 3^1 factorial, respectively. The linear system

$$\begin{aligned} A_1 t_1 &= \underline{c}_{1i} \\ A_2 t_2 &= \underline{c}_{2i}, \quad \text{for } (i = 1, 2, 3) \end{aligned}$$

satisfies the conditions in Theorem 2. Therefore the design

$$T = T_{11} \otimes_f T_{21} + T_{12} \otimes_f T_{22} + T_{13} \otimes_f T_{23}$$

$$= \begin{pmatrix} 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 1 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 \end{pmatrix}$$

$$T = T_{11} \otimes_f T_{21} + T_{12} \otimes_f T_{22} + T_{13} \otimes_f T_{23}$$

$$= \begin{pmatrix} 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 \end{pmatrix}$$

obtained as in Eq. 10 is an orthogonal design for estimating $\underline{F}$. Here number of treatments is $N = 3 \times 4 = 12$; the number of parameters in $\underline{F}$ is $\nu = 12 = N$. The design T is a saturated orthogonal design.

Case 2. Consider a $2^4 \times 3$ factorial experiment. The factorial effects of interest given in the vector $\underline{F}$ as

$$\underline{F}' = (0, 1, 2, 3, 4, 5, 5^2, 12, 13, 23, 15, 25, 35, 45, 15^2, 25^2, 35^2, 45^2)$$

are such that the two-factor interactions are either within the subgroup $\{1, 2, 3\}$ or are between the subgroups $\{1, 2, 3, 4\}$ and $\{5\}$. Let $T_1 = [T_{11}:T_{12}:T_{13}]$ and let T_{1i} ($i = 1, 2, 3$) with size (4×8) be the solutions to the linear $A_1 t_{1i} = \underline{c}_{1i}$, where $A_1 = (1111)$ and $\underline{c}_{1i} = 0$. Let $T_2 = [T_{21}:T_{22}:T_{23}]$, where T_{2i} ($i = 1, 2, 3$) with size (1×3) are the solutions to the linear $A_2 t_{2i} = \underline{c}_{2i}$, where $\underline{t}_2' = (t_4)$, $A_2 = (1)$, and $\underline{c}_{2i} = 0$. Here $n = 4$, $m = 1$, $f = 3$. The linear system

$$A_1 t_{1i} = \underline{c}_{1i}$$

$$A_2 t_{2i} = \underline{c}_{2i}, \quad \text{for } (i = 1, 2, 3)$$

satisfies the conditions in Theorem 2. Therefore the design (see Equation below) obtained as in Eq. 10 is an orthogonal design for estimating $\underline{F}$. Here number of

treatments is $N = 3 \times 8 = 24$, and the number of parameters in $\underline{F}$ is $\nu = 18$.

Now consider orthogonal arrays for mixed designs. An $(n + m) \times N$ matrix T is said to be an $OA[(n + m), N, 2^n \times 3^m, d]$, if:

1. Its first n rows have elements from the set $\{0, 1\}$ and the last m rows have elements from the set $\{0, 1, 2\}$.
2. Any $d \times N$ submatrix T_0 of T has the property that all possible columns vectors of T_0 occur in T_0 with the same frequency.

It is easy to see that the following matrix H is an $OA(5, 12, 2^4 \times 3, 2)$:

$$H = \begin{pmatrix} 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 \end{pmatrix}$$

Now we use the matrix H to generate the following orthogonal designs.

Case 3. Consider a $2^5 \times 3$ factorial experiment. The factorial effects given in the vector

$$\underline{F}' = (0, 1, \dots, 5, 6, 6^2, 16, 26, 36, 46, 56, 16^2, 26^2, 36^2, 46^2, 56^2)$$

have the property that the two-factor interactions are between the subgroups $\{1, 2, 3, 4, 5\}$ and $\{6\}$. Let C_1 (4×12) be the first four rows of H , and let $T_1 = [T_{1,1}:\dots:T_{1,12}]$, $T_{1,i}$ ($i = 1, \dots, 12$) with size (5×2) be the solutions to the linear $A_1 t_{1i} = \underline{c}_{1,i}$, where $\underline{c}_{1,i}$ is the i th column of C_1 , and

$$T = T_{1,1} \otimes_f T_{2,1} + \dots + T_{1,12} \otimes_f T_{2,12}$$

$$= \begin{pmatrix} 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 \end{pmatrix}$$

$$A_1 = \begin{pmatrix} 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{pmatrix}$$

Let $C_2(1 \times 12)$ be the last row of H . Let $T_2 = [T_{2,1}, \dots, T_{2,12}]$, and let $T_{1,i} (i = 1, \dots, 12)$ with size (1×1) be the solutions to the linear $A_2 t_2 = c_{2,i}$ over $GF(3)$, where $A_2 = (1)$, $t_2 = t_6$, $c_{2,i}$ is the i th column of C_2 . The linear system

$$\begin{aligned} A_1 t_1 &= c_{1i} \\ A_2 t_2 &= c_{2i}, \quad \text{for } (i = 1, 2, 3) \end{aligned}$$

satisfies the conditions in Theorem 2. Therefore the design (see Equation above) obtained as in Eq. 10 is an orthogonal design for estimating $\underline{F}$. Here the number of treatments is $N = 12 \times 2^{5-4} \times 3^{1-1} = 24$, and the number of parameters in $\underline{F}$ is $\nu = 18$.

Case 4. Consider a $2^4 \times 3^2$ factorial experiment. The factorial effects of interest given in the vector

$$\underline{F}' = (0, 1, \dots, 5, 6, 5^2, 6^2, 16, 26, 36, 46, 56, 16^2, 26^2, 36^2, 46^2, 56^2, 5^2 6, 5^2 6^2)$$

are such that the two-factor interactions are between the subgroups $\{1, 2, 3, 4, 5\}$ and $\{6\}$. Take $T_1 = H$. Therefore the design (see Equation below) is an orthogonal design for estimating $\underline{F}$. Here the number of treatments is $N = 12 \times 3 = 36$, and the number of parameters in $\underline{F}$ is $\nu = 21$.

APPLICATION OF MIXED FACTORIAL DESIGN IN BIOMEDICAL RESEARCH

In this section, we consider two examples in the biomedical research area, in which factorial experiments are widely used for screening the important factors or studying the higher-factor interactions.

Example 1: Allele-Specific Polymerase Chain Reaction for Screening Point Mutation

Polymerase chain reaction is a powerful biological technique to facilitate molecular analysis, including the DNA

diagnosis and identification of a human being's genetic disease. Many components affect a PCR process. In addition, there may be complex interactions among the components of PCR. Factorial designs are considered as cost-effective techniques to achieve optimization of PCR.

In an experiment we consider, the PCR yield is determined by two procedures, DNA extraction and PCR conditions. The five most important factors (or components) are identified in the PCR array as follows:

1. F_1 = autoclave, the degree of autoclave blood spots prior to DNA extraction.
2. F_2 = DNA extraction, the methods of extracting human genetic DNA from dried blood spots.
3. F_3 = number of blood spots in each DNA extraction tube.
4. F_4 = template DNA, the volume of template DNA used in the PCR.
5. F_5 = magnesium concentration.

The first four factors, F_1 to F_4 , take on two levels, coded as $\{0, 1\}$. The last factor, F_5 (magnesium), takes on three levels, coded as $\{0, 1, 2\}$. Prior experience indicates that there may be interactions among autoclave, DNA extraction, and number of blood spots in each of the DNA levels. Also, magnesium is very active, and it may interact with other factors. Therefore we need to estimate the two-factor interactions within the subgroup $\{F_1, F_2, F_3\}$ and the two-factor interactions between the subgroups $\{F_1, F_2, F_3, F_4\}$ and $\{F_5\}$, besides the general mean and all the main effects. The parameter vector of interest can be written as

$$\underline{F}' = (\mu, F_1, F_2, F_3, F_4, F_5, F_5^2, F_1 F_2, F_1 F_3, F_2 F_3, F_1 F_5, F_2 F_5, F_3 F_5, F_4 F_5, F_1 F_5^2, F_2 F_5^2, 2 F_3 F_5^2, F_4 F_5^2)$$

By Case 2 in "Orthogonal Designs for Mixed $2^n \times 3^m$ Factorial Experiments," there exists an orthogonal design with 24 treatment combinations to estimate the parameter vector $\underline{F}$. The orthogonal design is presented above. Here the 24 columns correspond to the 24 treatments of different factorial combinations, which can give optimal estimates of 18 parameters in $\underline{F}$.

$$\begin{aligned} T &= T_1 \otimes_f (0, 1, 2)' \\ &= H \otimes_f (9, 1, 2)' \end{aligned}$$

$$= \begin{pmatrix} 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 & 2 \end{pmatrix}$$

Treatment index	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24

Example 2: Drug Interaction in a Clinical Study

It is very common for patients with life-threatening diseases, such as AIDS and cancer, to undergo multiple therapies. Suppose, in a clinical study, we want to study the drug interactions among patients in different demographic groups. The following factors affect the outcome of therapy:

1. F_1 = gender of patients, with two levels (male = 0, female = 1).
2. F_2 = drug A, with two doses, denoted as 0 and 1.
3. F_3 = drug B, with two doses, denoted as 0 and 1.
4. F_4 = drug C, with two doses, denoted as 0 and 1.
5. F_5 = severity of the disease, with three levels (mild = 0, moderate = 1, severe = 2) (see 1st equation above).
6. F_6 = newly approved drug D, with three doses, denoted as (0, 1, 2).

The objective is to study the synergistic or antagonistic effects between newly approved treatment D and existing treatments A, B, and C in male and female patients with different levels of severity of the disease. Based on previous experiments, it is believed that interactions occur between D and A, B, C. The three-factor interactions can be ignored. We are interested in estimating all the main effects for each factor and two-factor interactions between drug D and the rest of the factors. Therefore the 21 factor effects of interest are given in the vector

$$\underline{F}' = (\mu, F_1, \dots, F_6, F_1^2, F_2^2, F_3^2, F_4^2, F_5^2, F_6^2, F_1F_2, F_1F_3, F_1F_4, F_1F_5, F_1F_6, F_2F_3, F_2F_4, F_2F_5, F_2F_6, F_3F_4, F_3F_5, F_3F_6, F_4F_5, F_4F_6, F_5F_6, F_1^2F_2^2, F_1^2F_3^2, F_1^2F_4^2, F_1^2F_5^2, F_1^2F_6^2, F_2^2F_3^2, F_2^2F_4^2, F_2^2F_5^2, F_2^2F_6^2, F_3^2F_4^2, F_3^2F_5^2, F_3^2F_6^2, F_4^2F_5^2, F_4^2F_6^2, F_5^2F_6^2)$$

By Case 4 in "Orthogonal Designs for Mixed $2^n \times 3^m$ Factorial Experiments," the following design is an orthogonal design for estimating $\underline{F}$: (See Equation 2nd equation above) where the 36 columns of factor level combinations are the treatments in the orthogonal design.

CONCLUSION

Notice that the numbers of treatment combinations required by a full or fracture factorial design increases geometrically as the numbers of factors increases. This leads to the major interest of factorial design to be efficient. One may generate design structure through assistance of a modern computer. However, without knowledge of advanced mathematics in finite geometries, number theories, group theories etc., it may become an exercise of trial and error to obtain an experimental design. In practice, the higher factors and high factor interactions do exist even though we wishfully think they shall be negligible. In order to give the estimates of higher factor effects which are uncorrelated with each other, one can use orthogonal arrays with higher strength. From the above discussions and examples, factorial design is an effective approach for quantitatively studying cause and effect relationship.

Abstract

The false discovery rate is defined as the expected proportion of false positives among the total number of positives. This entry provided statistical models for determining the FDR.

INTRODUCTION

Multiple testing is a classical problem for many high-dimensional data sets. The breakthrough of technology for image analysis or genomics has given a new interest for this question. A classical application is microarrays. This technology is part of a new class of biotechnologies that allow the monitoring of the expression level of thousands of genes simultaneously. Among the applications of microarrays, the identification of differentially expressed genes, i.e., genes whose expression is associated with the status of patients (treatment/control, for example) is an important one. The biological question of identifying differentially expressed genes can be restated as a two-sample hypothesis testing procedure: Is the gene differentially expressed between the two situations? However, when thousands of genes in a microarray data set are evaluated simultaneously by fold changes and significance tests approach, multiple testing problems immediately arise and lead to many false positive genes. In this “one-by-one gene” strategy the probability of detecting false positives rises sharply.

In this article we focus on differentially expressed genes; but the proposed results are applicable for all kinds of null hypothesis. In the framework of test theory, most of the desirable properties are defined for a single test: type I or II error, sensitivity, power, specificity, etc. In the case of multiple testing, extensions are far from obvious.

A small example illustrates the problem of multiple testing. Let us consider that m_0 genes among m are not differentially expressed, and that all the tests are performed with level α . Let us assume independent tests. Then the number of false positives (V) is a random variable, with binomial probability distribution

$$V \sim B(m_0, \alpha)$$

This simple modeling leads to the conclusion that the expected number of false positives when m_0 true null hypothesis are tested simultaneously is $E(V) = m_0 \alpha$. Regarding the high number of tests performed in microarray experiments (for instance $m = 10,000$), even if no gene is differentially expressed (in reality), a level $\alpha = 0.05$ leads to declare 500 genes as differentially expressed. The purpose of multiple testing is then to control the global risk of the procedure.

ERROR CRITERIA FOR MULTIPLE COMPARISONS: FALSE DISCOVERY RATE AND RELATED QUANTITIES

Definition

Consider a multiple testing situation in which m tests are being performed. The m genes can be classified according to the following 2×2 table:

	H_0 not rejected	H_0 rejected	Total
H_0 true	U	V	m_0
H_0 false	T	S	m_1
Total	W	R	m

To date, the aim of the main approaches taking into account the multiple testing problem has been to control the familywise error rate (FWER) that is defined as the probability of falsely reject at least one null hypothesis

$$\text{FWER} = \Pr[V \geq 1]$$

As an example, the Bonferroni procedure, which is the simplest and the most known procedure controlling the

FWER, consists in performing each test at level $\alpha^* = \alpha/m$. Then

$$\begin{aligned} \text{FWER} &= \Pr\{V > 0\} = \Pr\left(\min_{i \in I} (P_i) \leq \alpha^*\right) \\ &= \Pr\left(\bigcup_{i \in I} \{P_i \leq \alpha^*\}\right) \leq \sum_{i \in I} \Pr(P_i \leq \alpha^*) \\ &= m_0 \alpha^* \leq m \alpha^* = \alpha \end{aligned}$$

where $I = \{i \text{ such that } H_{0i} \text{ true}\}$.

However, as argued by Benjamini and Hochberg,^[1] controlling the FWER in multiple testing settings may not always be appropriate. As an alternative and less stringent concept of error control they introduced the false discovery rate (FDR). The main interest of controlling the FDR is that it is an appealing quantity that leads to more powerful procedures than those relying on the FWER. The FDR is defined as the expected proportion of false positives among the total number of positives

$$\text{FDR} = E(Q), \quad \text{where } Q = \begin{cases} V/R & \text{if } R > 0 \\ 0 & \text{if } R = 0 \end{cases}$$

Broadly speaking, the FDR corresponds to the proportion of rejections that is incorrect.

It is worth noting that a dual quantity of the FDR is the false non-discovery rate (FNR) as defined by Genovese and Wasserman.^[2]

If FWER is the oldest and easiest extension to the classical testing procedure that is relevant for decisional studies (e.g., clinical trials), the FDR seems particularly well suited for exploratory analysis. In practice, the FDR leads to more powerful procedures than those relying on the FWER and gives an idea of the proportion of false positive hypothesis that a practitioner can expect if the experiment is done an infinite number of time. However, being an expectation, it gives very little information about the proportion of false discovery hypothesis in a given experiment.

In their seminal paper, Benjamini and Hochberg^[1] discussed another criterion, later called the positive false discovery rate (pFDR) by Storey, Taylor, and Siegmund^[3] and defined as $\text{pFDR} = E(V/R | R > 0)$. However, Benjamini and Hochberg^[1] did not consider this criterion as it cannot be controlled since under the complete null hypothesis (all null hypothesis tested are true), all significant results (if there are significant ones) are necessary false discoveries. So, it is impossible to insure that $\text{pFDR} < \alpha$ if $\alpha < 1$.

In 2001, Storey^[4] demonstrated that if the test statistics T is independent and identically distributed for a fixed rejection region Γ , which is the same for every test, the pFDR is defined as

$$\begin{aligned} \text{pFDR}(\Gamma) &= \Pr(\mathcal{H}_0 \text{ true} | T \in \Gamma) \\ &= \frac{\Pr(\mathcal{H}_0 \text{ true}) \Pr(T \in \Gamma | \mathcal{H}_0 \text{ true})}{\Pr(T \in \Gamma)} \end{aligned}$$

However, from its definition, the pFDR is obviously related to the FDR through $\text{pFDR} = \text{FDR} / \Pr(R > 0)$. As $\Pr(R > 0)$ tends to 1 when the number of tested hypotheses tends to infinity, these two criteria are asymptotically equivalent.

Two other quantities related to the FDR were also introduced: the q -value and the local FDR. The q -value has been introduced by Storey^[4] and measures the minimum FDR that is incurred when considering that a test is significant. The FDR that has been introduced by Efron et al.^[5] is defined as the FDR in an infinitesimal interval. It may be interpreted as an estimate of the FDR attached to each gene.

CONTROL AND ESTIMATION OF THE FDR

Control of the FDR

In their seminal paper, Benjamini and Hochberg^[1] developed a step-up procedure (here denoted BH) under the hypothesis of independency that controls FDR at a prespecified level α .

The BH procedure works as follows: Suppose $P_1, \dots, P_m$ are p -values for the m tests. Let $P_{(1)} < \dots < P_{(m)}$ denote the ordered p -values. Calculate $k = \max_i \{P_{(i)} \leq \alpha i/m\}$. The procedure rejects all null hypothesis for which $P_{(i)} \leq P_{(k)}$. If the tests are independent, this procedure ensures that

$$\text{FDR} \leq \frac{m_0}{m} \alpha \leq \alpha$$

Benjamini and Yekutieli^[6] extended the procedure to the case of dependent tests. Genovese and Wasserman^[2] and Storey, Taylor, and Siegmund^[3] provided additional results on control of FDR based on martingales.

Estimation of the FDR

Note that the number of false positives and the total number of positive genes depend on a threshold t fixed by the practitioner thus the FDR is also a function of this threshold. In our context, the threshold will be given by ordered p -values

$$V(t) = \#\{\mathcal{H}_0 \text{ true and } p_i \leq t, i = 1, \dots, m\}$$

$$R(t) = \#\{p_i \leq t, i = 1, \dots, m\}$$

If the procedure stops at threshold t , the observed number of positives is g

$$R(t) = g$$

The problem is rather in the calculus of the expected number of false positives.

As it is known that under $\mathcal{H}_0$ p -values are uniformly distributed over $[0,1]$ we have

$$\Pr\{P_i \leq t\} = \mathcal{H}_0 t$$

The expectation of the number of false positives is then $E[V(t)] = m_0 t$, m_0 being the number of true non-differentially expressed genes, which is unknown. Thus a natural estimate of FDR is

$$\widehat{\text{FDR}}(t) = \frac{m_0 t}{g}$$

As the number of true non-differentially expressed genes m_0 is unknown, a classical strategy^[1] is to replace it with m that is known but larger than m_0 . If the aim of the procedure is to control the FDR at level α , then the stopping rule will be

$$P_{(g)} < \frac{g\alpha}{m}$$

Benjamini and Hochberg^[1] and Storey, Taylor, and Siegmund^[3] used convexity argument to prove that $E(\widehat{\text{FDR}}(t)) \geq \text{FDR}(t)$.

As seen previously, $\text{pFDR}(\Gamma) = \Pr(\mathcal{H}_0 \text{ true} | T \in \Gamma)$ that can be reexpressed from the Bayes formula

$$\begin{aligned} \text{pFDR}(\Gamma) &= \Pr(\mathcal{H}_0 \text{ true} | T \in \Gamma) \\ &= \frac{\Pr(T \in \Gamma | \mathcal{H}_0 \text{ true}) \Pr(\mathcal{H}_0 \text{ true})}{\Pr(T \in \Gamma)} \end{aligned}$$

The method proposed by Storey^[7] and Storey and Tibshirani^[8] for estimating the pFDR is based on the separate estimation of the three terms: $\Pr(T \in \Gamma) | \mathcal{H}_0 \text{ true}$, $\Pr(T \in \Gamma)$, and $\pi_0 = \Pr(\mathcal{H}_0 \text{ true})$, which is the probability for a gene to not be differentially expressed. Different methods based on the distribution of the test statistics or the corresponding p -values with or without making any assumption on the distribution related to the modified genes have been proposed. It is worth noting that without any assumption on the distribution of modified genes, only an upper bound estimator of π_0 can be obtained, leading to a conservatively biased estimator for the pFDR.

Estimation Based on the Marginal Density of the Statistics Without Parametric Model on the Modified Gene Distribution

Distribution of the Gene Statistics. In their seminal paper, Tusher, Tibshirani, and Chu^[9] introduced significance analysis of microarrays (SAM) as a statistical technique for finding significant genes in microarrays. This technique aims to estimate the FDR based on the distribution of particular test statistics (T).^[9] The principle is to estimate the quantities $\Pr(T \in \Gamma | \mathcal{H}_0 \text{ true})$, $\Pr(T \in \Gamma)$, and π_0 using resampling techniques^[10] such as:

- The empirical proportion of rejected hypothesis is used to estimate $\Pr(T \in \Gamma)$.
- $\Pr(T \in \Gamma | \mathcal{H}_0 \text{ true})$ is estimated with resampling techniques.^[10]
- π_0 is estimated by $\min(\{\#T \in [\hat{q}_{25} - \hat{q}_{75}]\} / (0.5m); 1)$.

where $\hat{q}_{25}$ and $\hat{q}_{75}$ are the first and third quartiles of the distribution of the test statistics estimated under the null hypothesis with resampling techniques.

More details on the method can be found at the SAM Website: <http://www.stat.stanford.edu/~tibs/SAM/>

Distribution of the p -values. From the distribution of the p -values, other procedures have been proposed that rely on the hypothesis that the p -values are uniformly distributed under the null hypothesis, so that $\Pr(P_i \leq t | \mathcal{H}_0 \text{ true})$ is equal to t . Thus:

$$\text{pFDR}(t) = \frac{\pi_0 t}{\Pr(P_i \leq t)}$$

where the main problem is to estimate the quantity π_0 .

Let f be the marginal probability density function (pdf) of P , f_0 the conditional pdf of P under the null hypothesis, and f_1 be the conditional pdf of P under the alternative hypothesis

$$f(p) = \pi_0 f_0(p) + (1 - \pi_0) f_1(p)$$

Under the null hypothesis, the P -values are supposed to be uniformly distributed on $[0, 1]$ so that $f_0(p) = 1_{[0,1]}(p)$. As $(1 - \pi_0) f_1(p)$ is non-negative, $f(p)$ is an upper bound of π_0 whatever p . Assuming that f_1 (which could itself be a mixture of distribution) is a non-increasing function, the smallest upper bound for π_0 based on previous equation is $f(1)$. Thus, assuming that $f_1(1) = 0$, an unbiased estimator of $f(1)$ provides a conservatively biased estimator of π_0 .

Considering

$$\hat{\pi}_0(\lambda) = \frac{\#\{P_i > \lambda; i = 1, \dots, m\}}{m(1 - \lambda)}$$

as a function of λ , Storey and Tibshirani^[8] proposed the usage of a cubic spline based method to estimate the quantity $\lim_{\lambda \rightarrow 1} \hat{\pi}_0(\lambda)$. Let F be the marginal cumulative distribution function of P ; this estimator can be viewed as $\hat{\pi}_0(\lambda) = [1 - \hat{F}(\lambda)] / (1 - \lambda)$. Then, the estimated quantity is:

$$\lim_{\lambda \rightarrow 1} \hat{\pi}_0(\lambda) = \lim_{\lambda \rightarrow 1} \frac{1 - \hat{F}(\lambda)}{1 - \lambda} = \frac{d\hat{F}}{d\lambda}(1) = \hat{f}(1)$$

Relying on the same framework, two procedures named BUM^[11] and SPLOSH^[12] have been recently proposed. The first one is based on a Beta-Uniform modeling approach, in which the parameters are estimated using the maximum likelihood method, and $\hat{\pi}_0 = \hat{f}(1)$. The second one is based on a local regression method^[13] to obtain a smooth estimate of f in a transformed space (for more details on the transformation used, see Ref. [12]).

Another class of estimators named LBE (Location Based Estimator) has been recently proposed by Dalmaso, Broet, and Moreau^[14] that is based on the expectation of the p -values. At first, let us note that

$$\frac{E(P)}{E_0(P)} = \pi_0 + (1 - \pi_0) \frac{E_1(P)}{E_0(P)}$$

where $E_0(P)$ and $E_1(P)$ are the expectations of the conditional distribution of P under the null and the alternative hypothesis, respectively.

Since the p -values are uniformly distributed under the null hypothesis, $E_0(P) = 1/2$. Then, $\hat{\pi}_0 = 2 \frac{1}{m} \sum_{i=1}^m P_i$ an unbiased estimator of $E(P)/E_0(P)$, is a conservatively biased estimator of π_0 . Under suitable conditions on a function φ the authors show that a transformation of the p -values can lead to a less biased estimator of π_0 . In the set of the suitable functions, they consider the functions $\varphi(P) = -\ln(1-x)^n, n \in \mathbb{N}$, and they show that these functions lead to a family of estimators for which the bias for π_0 is decreasing with n . As under the null hypothesis, $-\ln(1-P)$ follows an exponential distribution with parameter 1, $E_0([-\ln(1-P)]^n) = n!$, and the proposed family of estimators is:

$$\hat{\pi}_{0(n)} = \frac{\frac{1}{m} \sum_{i=1}^m [-\text{Log}(1-p_i)]^n}{n!}, \quad n \in \mathbb{N}$$

For this family of estimators, an upper bound of the asymptotic variance of the estimator is $[(\frac{n}{2n}) - 1]/m$. As there is a balance between bias (decreasing as n increases) and variance (increasing as n increases), for a specified number m of tested hypotheses, the authors intended in practice to choose n according to a threshold l for the variance's upper bound such as

$$n = \max \left(1, \max \left(n \in \mathbb{N} \mid \frac{(\frac{n}{2n}) - 1}{m} \leq l \right) \right)$$

Then, the estimator $\hat{\pi}_0$ is plugged in the FDR formula.

The estimators LBE, QVALUE, BUM, and SPLOSH were compared through simulations. This simulation study has shown that BUM and SPLOSH procedures underestimate π_0 in most of cases, leading to an underestimation of the estimator of the FDR. The simulation study has also shown that, as compared to the procedure QVALUE, the procedure LBE has the smallest mean square error in most cases.

Estimation Based on the Marginal Density of the Statistics with Parametric Model on the Modified Gene Distribution

In the framework of the mixture model with hypothesis on the modified gene distribution, frequentist and Bayesian approaches have been proposed.

A key point is to note that the distribution of the p -values is uniform on the interval $[0,1]$ regardless of the statistical test used (as long as that test is valid) and sample size. In contrast, under the alternative hypothesis, the distribution of p -values is concentrated near 0 and null near 1. Allison et al.^[15] proposed the use of finite mixture models of beta laws (because a beta distribution with parameter 1 and 1 is a uniform distribution). They

estimated the number of component as well as the parameters. BUM^[12] is a restricted version of this work. This work has been extended to the mixture of a uniform and a beta distribution by Liao et al.^[16] Other approaches based on mixture models in a Bayesian framework have also been proposed (for a few: 1) detecting differential gene expression with a semiparametric hierarchical mixture method^[17] or 2) a mixture model-based strategy for selecting sets of genes in multiclass response microarray experiments^[18]).

THE LOCAL FDR

The value of 1%, 5% or 10% for the FDR, which determines the threshold t , is arbitrary. Storey^[7] has stressed the importance of assessing the own measure of significance to each feature. They intended to use the q -value

$$\frac{\hat{m}_0 P_i}{R_i}$$

where P_i is the p -value of the ordered gene i , and R_i is the total number of rejected genes with the threshold $t = P_i$.

The q -value is appealing because it gives a measure of significance that can be attached to each gene; but it must be stressed that it is not an estimate of the probability for the gene to be a false positive. The q -value is generally lower than the latter because it is computed using all the genes that are more significant than gene i . Obviously a gene whose p -value is near to the threshold t does not have the same probability to be differentially expressed than a gene whose p -value is close to 0. Therefore the q -value gives a too optimistic view of the probability for the gene to be a false positive. Therefore it is interesting to obtain an estimate of the FDR attached to each gene from an inferential point of view and without any assumption about the distribution of the p -values under H_1 . It is the idea of the local FDR introduced by Efron et al.^[5,19]

The general model of mixture can be written as $f(t) = p_0 f_0(t) + (1-p_0) f_1(t)$, where p_0 is the fraction of differentially expressed genes, and f_0 and f_1 are the densities of the statistics for non-differentially and differentially expressed genes, respectively. Bayes' theorem generates, under this model, for each gene the probability of no differential expression, given that the value of the statistic is the local FDR and is defined as

$$\frac{p_0 f_0(t)}{f(t)}$$

The local FDR is the a posteriori probability of effect for individual genes. In Ref. [5], the ratio $f_0/f(t)$ is estimated by bootstrap.

We now present an estimation method developed in Aubert et al.^[20]

Let us consider a particular experiment. We observe the differential expression of the genes and compute the

p -values P_i . For simplicity, we consider the ordered p -value and we drop the bracket in the subscript of P_i . At first we assume that m_0 the number of genes under $\mathcal{H}_0(i)$ is known. This assumption will be relaxed later.

The P_i are not random, but the status of the gene associated with the P_i is an unobserved value. It is the same framework that points process on a lattice.^[21] In fact we observe $R(t)$, the sum of two marked point process. The first one $V(t)$ is a counting process associated with non-differentially expressed gene. As the p -value under $\mathcal{H}_0$ is uniformly distributed, $V(t)$ is distributed as a binomial law with parameter m_0 and t . $S(t)$ is the counting process associated with gene under H_1 and very few can be said about its distribution. One may expect that intensity of $S(t)$ is higher around 0 than around 1.

The true parameter of interest for a given experiment is $V(t)$. Using basic properties of binomial law, we obtain

$$P(V(t) \geq v) = \sum_{i \geq v} C_{m_0}^i (m_0 t)^i (1 - m_0 t)^{m_0 - i}$$

From a practical point of view it gives bound to the number of false positive genes selected with a threshold value of t for a given experiment.

It is more useful to get results bounds on a given experiment than on expectation on all possible experiments. Following the same idea, it would be more useful to have results gene by gene rather than globally among all genes. Obviously a gene whose p -value is near the threshold t does not have the same probability to be differentially expressed than a gene whose p -value is closed to 0. The question can be restated as estimation of the ratio of the intensities around a given P_i . Let FDR_i be the local ratio of intensity around P_i . The naive estimate $\hat{E}(V_i)$ is:

$$\hat{E}(V_i) = \frac{m_0 (P_{i+1} - P_{i-1})}{2} \quad (1)$$

It corresponds to an interval around P_i . This estimate is unbiased if the points are uniformly distributed on $[0,1]$. However it is a very variable estimator. This fact is very well known in point process literature.^[21] A more stable estimate given in Ref. [20] is very close to the moving average estimate and corresponds to a generalization of Eq. (1).

Using the definition of FDR_i , it is direct to obtain

$$\sum_{i \leq j} \widehat{\text{FDR}}_i = \widehat{\text{FDR}} \left(\frac{P_j + P_{j+1} - P_1}{2} \right)$$

It is not a strong assumption to assume $p_1 \approx 0$.

An approximation to $\mathbb{P}(V_i = 1)$ can be obtained by noting that $\mathbb{E}(V_i) = \sum_k k \mathbb{P}(V_i = k) \approx \mathbb{P}(V_i = 1)$ for a small enough interval. As we omit positive terms, $\mathbb{E}(V_i) \geq \mathbb{P}(V_i = 1)$. This quantity can give a guideline for the choice of a threshold. Using cost of the experiment, cost of false positive gene

validation, and the profit of discovering a differentially expressed gene, it is direct to compute the optimal strategy for choosing the threshold.

As an interesting application it is possible to compute the FDR associated with a class of gene (for example, genes known to be involved in a given regulation network). These genes do not need to be consecutive for their p -values. It gives the opportunity to compute the FDR of any given group of clones or genes. The following sections demonstrate how the local FDR can be used on several classical datasets.

Local FDR on Golub Data Set

Golub et al.^[22] were interested in identifying genes that are differentially expressed between patients with two types of leukemias (ALL, and AML). Gene expression levels were measured using Affymetrix high-density chips containing 6817 human genes. The learning set comprises 27 ALL cases and 11 AML cases.

Data are available in the R multtest package. We used the preprocessing proposed by the authors and the p -values based on random permutations of the ALL/AML labels on Welch t —statistics for each gene^[23] on the 3051 remaining genes. m_0 is estimated with bootstrap method as suggested by Storey and Tibshirani and implemented in the library GeneTS of software R.

Fig. 1(A) presents the $\widehat{\text{FDR}}(i)$ for ordered genes, and 1(B) presents the smooth curves obtained using lowess with a span of 0.2 and an adaptative moving average method.

We can see that there is an abrupt change of the local FDR around $t = 0.15$ in the smooth local FDR. This may be an indication about the threshold. Fig. 1(C) presents a zoom of Fig. 1(B) for the first 600 p -values. We can see in Fig. 1(C) that if we select the 438 (14%) top genes, we obtain a q -value equal to 0.0078 while the 438th gene has a local FDR equal to 0.027. It must be noticed that there is a big difference between the two measures of FDR because the numerous regulated genes with very small p -values have an important weight in the q -value, which is not the case of the local FDR [Fig. 1(C)].

The p -values have been obtained using random permutations. Therefore the p -values are discrete with several genes possessing the same p -value. Therefore the values of $\widehat{\text{FDR}}(i, \lambda)$ may be equal to 0 because the difference between two successive p -values is 0. The discrete structure of the p -values implies a departure from the theoretical continuous uniform distribution. This explains why the moving average smoothing creates discrete jumps that appear in Fig. 1(C).

If the distribution of the statistics under $\mathcal{H}_0$ is correct, the p -values are distributed as a uniform distribution over $[0,1]$. The empirical distribution is far from the uniform distribution. This makes the hypothesis of the t -statistics very questionable.

Fig. 1 Plots of the local FDR estimate for Golub data. *x*-axis: index of genes ordered along their *p*-values, *y*-axis: local FDR estimate. (A) raw values, (B) smooth estimates: moving average (discrete jumps), lowess (smooth curve); and (C) zoom on the first 600 genes of (B) moving average (discrete jumps), lowess (upper smooth curve), and *q*-value (lower thick smooth curve). Local FDR on Breast Cancer Data Set

Storey and Tibshirani^[8] have analyzed in detail data from Hedenfalk et al.^[24] on 15 microarrays on breast cancer. Using the same *p*-values, we have computed local FDR estimates. The three genes that have been analyzed in detail by Storey and Tibshirani^[8] are presented in Table 1.

One can see that the smooth local FDR estimate is greater than the *q*-value and gives a better idea of the probability that a gene is false positive. The difference of the two measures is sufficiently high to lead us to reconsider the scientific conclusion.

Fig. 2(A) presents the $\widehat{FDR}(i)$ for ordered genes, and 2(B) presents the smooth curves obtained using lowess with a span of 0.2 and moving average methods. The two smoothing methods give similar results. Setting $\lambda = 0.5$, Storey and Tibshirani^[8] estimate that 67% of the 3170 genes in the data are not differentially expressed. The asymptote near 1 of the smooth curve supports this estimation.

Local FDR on ApoAI Data

The goal of the study is to identify genes with altered expression in the livers of two lines of mice with very low high density lipoproteins (HDL) cholesterol levels compared to inbred control mice. The mouse model is the apolipoprotein AI (ApoAI) knock-out mice. ApoAI is a gene known to play a pivotal role in HDL metabolism. The statistical analysis is described in Dudoit, Shaffer, and Boldrick.^[23] Height clones are expected to be regulated between the control and the knock-out mice because they are clones of the ApoAI gene or of genes coregulated with ApoAI. The height clones are actually the eight top clones detected by the statistical tests. However there are other

Table 1 *p*-Value, *q*-Value and Local FDR Estimates for Three Genes in Hedenfalk data

Gene	<i>p</i> -value	<i>q</i> -value	Local FDR
MSH2	0.00005	0.0013	0.010
PDCD5	0.00048	0.022	0.033
CTGF	0.0036	0.049	0.098

following clones that seem statistically significant if we consider the *q*-value. We can see in Fig. 3(C) that the local FDR values are much higher than the *q*-values.

Fig. 3(A) presents the $\widehat{FDR}(i)$ for ordered clones and Fig. 3(B) presents the smooth curves obtained using lowess with a span of 0.2 and moving average methods. The two smoothing methods give different results at the two ends of the $[0,1]$ interval. The moving average method that uses a special adaptative algorithm for the ends gives a better smoothing. This is particularly important for the clones with a small *p*-value for which it is crucial to obtain good estimates of the probability of being false positives. The lowess smoothing does not work well for the 50 first clones. In this particular case the default smoothing parameter $f = 0.2$ is not well suited and should be lower. However if it is chosen too low, the smoothing will not be well suited for the rest of the curve.

There are two clones on the gene ApoAI. If we want to estimate the FDR of these two clones taken in a whole, we compute the sum of the smoothed local FDR of the two clones (the first and the height top clones) and obtain a local FDR for the gene Apo AI, which is equal to $(0 + 0.00048)/2 = 0.00024$. This example shows that it is possible to estimate the local FDR of any group of clones. This opportunity provided by the local FDR is certainly one of its major advantage with many potential applications.

Fig. 2 Plots of the local FDR estimate for Hedenfalk data. *x*-axis: index of genes ordered along their *p*-values, *y*-axis: local FDR estimate, (A) raw values; (B) smooth estimates: moving average (discrete jumps), lowess (smooth curve); and (C) zoom on the first 200 genes of (B) raw values (discrete jumps), moving average and lowess (smooth curves); and *q*-value (lower thick smooth curve). (View this art in color at www.informaworld.com.)

Fig. 3 Plots of the local FDR estimate for Apo-AI data. *x*-axis: index of clones ordered along their *p*-values, *y*-axis: local FDR estimate, (A) raw values; (B) smooth estimates: moving average (small discrete jumps), lowess (smooth curve); and (C) zoom on the 50 first genes of (B) raw values (discrete jumps), moving average (smooth curve) lowess (upper rectangular curve), and *q*-value (lower thick smooth curve). CONCLUSIONS

To date, statistical procedures devoted to the multiple testing problem mostly focused on controlling the FWER, which is the easiest extension to the classical test theory. However, controlling the FWER usually leads to a severe loss of power, particularly when analyzing high-dimensional data sets. In this context, the expected proportion of false discoveries among the total number of discoveries introduced in 1995 by Benjamini and Hochberg seems more appealing. Then, the FDR (and its related quantities) is nowadays widely used, and more and more procedures based on this criterion are developed.

While some procedures^[1,6] are based on a strict control of the FDR, many new procedures are focused on the estimation of this criterion through the relation between the *p*FDR and the FDR.^[7] In the framework of estimating procedures that do not make any assumption on the distribution

of modified genes, it is worth noting that all the proposed estimators necessarily overestimate the FDR. This problem is related to the fact that only an upper bound estimate can be obtained for the key quantity π_0 , which is the probability for a gene to be unmodified. Procedures based on distributional hypothesis for modified genes provide more accurate estimators of the FDR when the distributional hypotheses are true. However, these procedures are more complex to use in practice.

Among the extensions of the FDR, one of the most promising criterion is the local FDR introduced by Efron in 2001^[5] with an estimating procedure, which may be interpreted as an estimate of the FDR attached to each gene.

In the method proposed by Aubert et al.,^[20] the curve of the smoothed local FDR is an efficient tool to summarize the information about the number and the statistical significance of regulated genes, and may also be used to give an

indication about the validity of the statistical assumptions. Moreover it is a valuable tool to choose the threshold for separating the regulated genes from the unregulated one: One can choose a value of t maximizing the second derivative. Alternatively one can use a cost function and choose the threshold that minimizes the mean cost for a given cost function: Using cost of the experiment, cost of false positive gene validation, and the profit of discovering a differentially expressed gene, it is direct to compute the optimal strategy for choosing the threshold. One of the major interest of the local FDR is that it gives the opportunity to compute the FDR of any given group of clones (of the same gene) or genes pertaining to the same regulation network or the same chromosome.

GEE in Cancer Research

Sin-Ho Jung

Department of Biostatistics and Bioinformatics, Duke University, Durham, North Carolina, U.S.A.

Abstract

Cancer clinical trials often use a repeated measurement design in which individuals are randomly assigned to treatment arms and followed for measurements at intervals across a treatment period of fixed duration. In such studies, one of popular primary interests is the between-arm comparison of change rate in the expected value of a response variable over time. Because of the robustness to possible misspecification of the correlation structure among the repeated measurements, generalized estimating equation (GEE) method has been one of the most popular methods to fit the regression models and to test on the change rates. In this article, we review GEE method for analysis and sample size estimation methods for design of such trials. We consider the cases where the response variable is continuous or dichotomous.

Keywords: AR(1); Compound symmetry; Independent working correlation; Independent missing; Logit link; Missing completely at random; Monotone missing.

1 INTRODUCTION

Fisch et al.^[1] randomized advanced cancer outpatients between fluoxetine and placebo arms, and longitudinal assessments of quality of life (QOL) and depression were performed at baseline and every 3 to 6 weeks thereafter. The visit interval varied among patients and often depended on the schedule for anticancer therapy. Patients were assessed for 12 weeks, and complete assessment involved three to five sessions of data collection depending on the individual patients visit intervals. After the 12-week study period, the patients were given the option to continue the study drug for up to 9 more months. There were missing assessments too. The primary objective of this study was to compare the change rate of QOL and depression in advanced cancer patients over time. In this study, the outcome variables are continuous.

GENISOS (Genetics vs. Environment In Scleroderma Outcome Study) is an observational study designed as collaboration of the University of Texas-Houston Health Science Center with the University of Texas Medical Branch at Galveston and the University of Texas-San Antonio Health Science Center (Reveille et al.^[2]). Scleroderma, or systemic sclerosis, is a multisystem disease of unknown etiology characterized by cutaneous and visceral fibrosis, small blood vessel damage and autoimmune features (Medsger^[3]). The study subjects are regularly followed to check the occurrence pulmonary fibrosis. In this case, the outcome is a binary variable.

Typically repeated measurements from each subject are correlated. Furthermore, the subjects may skip some

visits so that the resulting data are subject to missing. GEE method (Liang and Zeger^[4]) has been one of the most popular methods to relate repeatedly measured outcome variable with covariates including the measurement time. If the missing is completely at random (Rubin^[5]), GEE method provides consistent regression estimator whether the working correlation structure specified for the repeated measurements is the true one.

In this article, we consider comparing the change rate of repeated measurements over time between two treatment groups. We propose a closed-form sample size formula for between-group comparison that can be used when designing a randomized longitudinal study with either continuous or binary outcome variable. Missing data attenuate the power of tests on the regression coefficients. Our formula account for the missing probabilities under independent or monotone missing pattern. We assume that the working independent correlation model is used in the final data analysis, but the sample size formula is derived to incorporate the influence of the true correlations, especially under AR(1) or compound symmetry.

The methods presented in this chapter can be used for randomized trials and observational studies for any diseases including cancer.

2 GENERALIZED ESTIMATING EQUATIONS

Suppose that n_k subjects are allocated to treatment group k ($k = 1, 2$), $n_1 + n_2 = n$. Let, for group k , $N_k = \sum_{i=1}^{n_k} m_{ki}$ denote

the total number of observations and $r_k = n_k/n$ the allocation proportion ($r_1 + r_2 = 1$).

For subject $i(i = 1, \dots, n_k)$ in group k , let y_{kij} denote the outcome variable at measurement time $t_{kij}(j = 1, \dots, m_{ki})$ with $\mu_{kij} = E(y_{kij})$ that is expressed as

$$g(\mu_{kij}) = a_k + b_k t_{kij},$$

where $g(\cdot)$ is a link function. To simplify the discussions, we use the identity link $g(\mu) = \mu$ for continuous outcome variables and the logit link $g(\mu) = \log\{\mu/(1-\mu)\}$ for binary outcome variables, but the generalization to the use of other links is simple.

The coefficient b_k represents the change rate per unit time in mean response if y is continuous and that in log-odds if y is binary. The measurement times may vary subject by subject due to missing measurements, patients' visits for measurements at unscheduled times, loss to follow-up, or other causes. In this article, we assume missing completely at random by Rubin (1976).

The repeated measurements ($y_{kij}, 1 \leq j \leq m_{ki}$) within each subject tend to be correlated. However, the true correlation structure is usually unknown or of secondary interest. Liang and Zeger^[4] proposed a consistent estimator, called the GEE estimator, based on a working correlation structure. Using either the identity or logit link, the GEE estimator $(\hat{a}_k, \hat{b}_k)$ based on the working independent structure solves $U_k(a, b) = 0$, where

$$U_k(a, b) = \frac{1}{\sqrt{n_k}} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} \{y_{kij} - \mu_{kij}(a, b)\} \begin{pmatrix} 1 \\ t_{kij} \end{pmatrix}$$

and $\mu_{kij}(a, b) = g^{-1}(a + b t_{kij})$.

2.1 Continuous Outcome Variable Case

In the continuous outcome variable case, we have a closed form solution to $U_k(a, b) = 0$

$$\hat{b}_k = \frac{\sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k) y_{kij}}{\sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k)^2}$$

and $\hat{a}_k = \bar{y}_k - \hat{b}_k \bar{t}_k$, where $\bar{t}_k = N_k^{-1} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} t_{kij}$ and $\bar{y}_k = N_k^{-1} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} y_{kij}$.

By Liang and Zeger^[4], as $n \rightarrow \infty$, $\sqrt{n_k}(\hat{b}_k - b_k) \rightarrow N(0, v_k)$ in distribution. Here v_k is consistently estimated by

$$\hat{v}_k = \frac{\sum_{i=1}^{n_k} \left\{ \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k) \hat{\epsilon}_{kij} \right\}^2}{\left\{ \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} (t_{kij} - \bar{t}_k)^2 \right\}^2}$$

where $\hat{\epsilon}_{kij} = y_{kij} - \hat{a}_k - \hat{b}_k t_{kij}$.

2.2 Binary Outcome Variable Case

Let $p_{kij} = \mu_{kij}$ in the binary outcome variable case. We have to solve the equation using a numerical method, such as the Newton-Raphson algorithm: at the l -th iteration,

$$\begin{pmatrix} \hat{a}_k^{(l)} \\ \hat{b}_k^{(l)} \end{pmatrix} = \begin{pmatrix} \hat{a}_k^{(l-1)} \\ \hat{b}_k^{(l-1)} \end{pmatrix} + n_k^{-1/2} A_k^{-1}(\hat{a}_k^{(l-1)}, \hat{b}_k^{(l-1)}) U_k(\hat{a}_k^{(l-1)}, \hat{b}_k^{(l-1)}),$$

where

$$A_k(a, b) = -n_k^{-1/2} \frac{\partial U_k(a, b)}{\partial(a, b)} = \frac{1}{n_k} \sum_{i=1}^{n_k} \sum_{j=1}^{m_{ki}} p_{kij}(a, b) q_{kij}(a, b) \begin{pmatrix} 1 & t_{kij} \\ t_{kij} & t_{kij}^2 \end{pmatrix}$$

$$p_{kij}(a, b) = g^{-1}(a + b t_{kij}) = \frac{e^{a + b t_{kij}}}{1 + e^{a + b t_{kij}}} \quad (1)$$

and $q_{kij}(a, b) = 1 - p_{kij}(a, b)$.

By Liang and Zeger^[4], for large n , $\sqrt{n_k}(\hat{a}_k - a_k, \hat{b}_k - b_k)^T$ is asymptotically normal with mean 0 and variance V_k that can be consistently estimated by

$$\hat{V}_k = A_k^{-1}(\hat{a}_k, \hat{b}_k) \hat{\Sigma}_k A_k^{-1}(\hat{a}_k, \hat{b}_k)$$

Where

$$\hat{\Sigma}_k = \frac{1}{n_k} \sum_{i=1}^{n_k} \left\{ \sum_{j=1}^{m_{ki}} \hat{\epsilon}_{kij} \begin{pmatrix} 1 \\ t_{kij} \end{pmatrix} \right\}^{\otimes 2},$$

$\hat{\epsilon}_{kij} = y_{kij} - p_{kij}(\hat{a}_k, \hat{b}_k)$ and $c^{\otimes 2} = c c^T$ for a vector c . Let $\hat{v}_k$ be the $(2, 2)$ -component of $\hat{V}_k$.

3 SAMPLE SIZE CALCULATION

Suppose that we want to test on the rate of change between two groups, i.e. $H_0: b_1 = b_2$. Based on the asymptotic results from the previous section, we can reject $H_0: b_1 = b_2$, in favor of $H_1: b_1 \neq b_2$ when

$$\left| \frac{\hat{b}_1 - \hat{b}_2}{\sqrt{\hat{v}_1 / n_1 + \hat{v}_2 / n_2}} \right| > z_{1-\alpha/2}, \quad (2)$$

where $z_{1-\alpha/2}$ is the $100(1 - \alpha/2)$ percentile of a standard normal distribution.

In this section, we derive a sample size formula for the two-sided α test (2) to detect $H_1: |b_2 - b_1| = d(>0)$ with power $1 - \beta$. When designing a study, we usually

schedule fixed visit times $t_1 < \dots < t_m$ for m repeated measurements from each subject. We often set $t_1 = 0$ for the baseline measurement time. When the study is conducted, however, the subjects may skip some visit times due to various causes, which results in missing values, or may not follow the visit schedule correctly so that the observed visit times may be variable. Jung and Ahn^[6] show through simulations in continuous outcome variable case that the sample size formula based on fixed measurement times is very accurate even when the observed measurement times are widely distributed around the scheduled times.

By simple algebra, we can derive a sample size formula to detect the specified difference $|b_2 - b_1| = d$ with power $1 - \beta$,

$$n = \frac{(z_{1-\alpha/2} + z_{1-\beta})^2 (v_1/r_1 + v_2/r_2)}{d^2}, \quad (3)$$

where $v_k = \lim_{n \rightarrow \infty} \hat{v}_k$. The expression of v_k is slightly different between continuous and binary outcome variable cases as shown in the following subsections.

In order to allow for missing, let δ_j denote the proportion of patients with observation at t_j and $\delta_{jj'}$ the proportion of patients with observations at both t_j and $t_{j'}$. Also, let $\rho_{jj'} = \text{corr}(y_{kij}, y_{kij'})$. We assume that the missing pattern and correlation structure are common in two treatment groups. We will discuss specific models for missing pattern and correlation structure in Section 4.

3.1 Continuous Outcome Variable Case

We assume that the continuous outcome variable has a constant variance $\text{var}(y_{kij}) = \sigma^2$ over time which is common between two treatment groups. Jung and Ahn^[6] show that $v_1 = v_2 = v$ is expressed as

$$v = \frac{\sigma^2(s^2 + c)}{s^4},$$

Where

$$s^2 = \sum_{j=1}^m \delta_j (t_j - \tau)^2$$

$$c_k = \sum_{j \neq j'} \sum \delta_{jj'} \rho_{jj'} (t_j - \tau)(t_{j'} - \tau)$$

and

$$\tau = \frac{\sum_{j=1}^m \delta_j t_j}{\sum_{j=1}^m \delta_j}.$$

Hence, (3) is simplified to

$$n = \frac{v(z_{1-\alpha/2} + z_{1-\beta})^2}{d^2 r_1 r_2}. \quad (4)$$

Note that we do not have to specify the true values for $\{(a_k, b_k), k=1,2\}$, but only the difference $|b_2 - b_1| = d$ in sample size calculation. The sample size is proportional to the variance of measurement error σ^2 , and decreases as r_1 approaches $1/2$.

Chow et al.^[7] propose a sample size formula for ANOVA with repeated measures. Their formula is similar to the formula for K-sample by Jung and Ahn^[8] under CS and no missing.

3.2 Binary Outcome Variable Case

Let $p_{kj} = a_k + b_k t_j$ denote the success probabilities under H_1 . Jung and Ahn^[9] show that

$$v_k = \frac{(s_k^2 + c_k)}{s_k^4},$$

Where

$$s_k^2 = \sum_{j=1}^m \delta_j p_{kj} q_{kj} (t_j - \tau_k)^2$$

$$c_k = \sum_{j \neq j'} \sum \delta_{jj'} \rho_{jj'} \sqrt{p_{kj} q_{kj} p_{kj'} q_{kj'}} (t_j - \tau_k)(t_{j'} - \tau_k),$$

and

$$\tau_k = \frac{\sum_{j=1}^m \delta_j p_{kj} q_{kj} t_j}{\sum_{j=1}^m \delta_j p_{kj} q_{kj}}.$$

As shown here, the sample size formula under binary outcome variable case depends on the probabilities $(p_{kj}, j=1, \dots, m)$ under H_1 , so that we need to specify all regression parameters $\{(a_k, b_k), k=1,2\}$. Let $d = b_2 - b_1$ denote the difference in slope between two groups under H_1 . If there exist pilot data for the control group (group 1), then we may use the estimates as the parameter values, a_1 and b_1 . If $t_1 = 0$ is the time of randomization, the intercepts in the two groups are set the same, i.e. $a_1 = a_2$. By setting $b_2 = b_1 + d$, we can specify all regression coefficients under H_1 .

If there are no pilot data available, we may specify the binary probabilities at the baseline, p_{11} , and at the end of follow-up, p_{1m} , for the control group. Then we obtain (a_1, b_1) by

$$b_1 = \frac{g(p_{1m}) - g(p_{11})}{t_m - t_1}. \quad (5)$$

$$a_1 = g(p_{11}) - b_1 t_1 = g(p_{11}).$$

And we set $a_2 = a_1$ (since $p_{11} = p_{21}$ at the baseline) and $b_2 = b_1 + d$.

4 MODELING MISSING PATTERN AND CORRELATION STRUCTURE

Calculation of n (or v_k) requires projection of the missing probabilities and the true correlation structure.

4.1 Missing Pattern

In order to specify $\delta_{jj'}$, we need to estimate the missing pattern. If missing at time t_j is independent of missing at time $t_{j'}$ for each patient, then we have $\delta_{jj'} = \delta_j \delta_{j'}$ and call this type *independent missing*.

In some studies, subjects missing at a measurement time may be missing at all following measurement times as in the labor pain study discussed in Introduction. This type of missing is called *monotone missing*. In this case, we have $\delta_{jj'} = \delta_{j'}$ for $j < j'$ ($\delta_1 \geq \dots \geq \delta_m$). In monotone missing case, one may want to specify the proportion of patients who will contribute exactly the first j observations, say η_j . Then, noting that $\eta_j = \delta_j - \delta_{j+1}$ for $j = 1, \dots, m-1$ and $\eta_m = \delta_m$, we can obtain δ_j recursively starting from δ_m . Note also that $\sum_j \eta_j = \delta_1$, which equals 1 if all patients have measurements at the first measurement time t_1 .

In summary, we consider two missing patterns as candidates to the true one: (a) independent missing, where $\delta_{jj'} = \delta_j \delta_{j'}$; (b) monotone missing, where $\delta_{jj'} = \delta_{j'}$ for $j < j'$ ($\delta_1 \geq \dots \geq \delta_m$).

4.2 Correlation Structure

Now, we specify the ‘true’ correlation structure $\rho_{jj'}$. A reasonable model for $\epsilon_{ij} = y_{ij} - g^{-1}(a + bt_{ij})$ may be

$$\epsilon_{ij} = u_i + e_{ij},$$

where u_i are subject-specific error terms with variance σ_u^2 and e_{ij} are serially correlated within-subject error terms with variance σ_e^2 and correlation coefficients $\tilde{\rho}_{jj'}$. Assuming that u_i and e_{ij} are independent, we have

$$\text{cov}(\epsilon_{ij}, \epsilon_{ij'}) = \sigma_u^2 + \sigma_e^2 \tilde{\rho}_{jj'}.$$

Often, the variation between subjects (σ_u^2) is much larger than that within subject (σ_e^2). In this case, we have

$$\text{cov}(\epsilon_{ij}, \epsilon_{ij'}) \approx \sigma_u^2$$

and a compounding symmetry (CS) correlation structure, $\rho_{jj'} = \rho$ for $j \neq j'$, may be a reasonable approximation to the true one.

On the other hand, if the variation within subject (σ_e^2) dominates over the variation between subjects (σ_u^2), then we will have

$$\text{cov}(\epsilon_{ij}, \epsilon_{ij'}) \approx \sigma_e^2 \tilde{\rho}_{jj'},$$

so that a serial correlation structure may be a reasonable approximation to the true one. One of the most popular serial correlation structure, especially when measurement times are not equidistant, is a continuous autocorrelation model with order 1, AR(1), for which $\rho_{jj'} = \rho^{|t_j - t_{j'}|}$.

We consider two correlation structures as candidate approximations to the true one: (i) CS, where $\rho_{jj'} = \rho$; (ii) AR(1), where $\rho_{jj'} = \rho^{|t_j - t_{j'}|}$.

5 EXAMPLES

For sample size calculation, following parameters need to be specified commonly in both continuous and discrete outcome variable cases:

- Type I and II errors α and β , respectively.
- Clinically significant difference, $|b_2 - b_1| = d$.
- Allocation proportion for group k , r_k .
- Correlation structure and the associated correlation parameter ρ , i.e. (i) $\rho_{jj'} = \rho$ for CS or (ii) $\rho_{jj'} = \rho^{|t_j - t_{j'}|}$ for AR(1).
- Proportion of patients with an observation at t_j , δ_j .
- Missing pattern: (a) independent missing ($\delta_{jj'} = \delta_j \delta_{j'}$) or (b) monotone missing ($\delta_{jj'} = \delta_{j'}$ for $j < j'$).

In addition, we need to specify $\sigma^2 = \text{var}(\epsilon_{ij})$ in the continuous outcome variable case, and the regression coefficients $\{(a_k, b_k), k = 1, 2\}$ under H_1 in the binary outcome variable case.

We demonstrate our sample size formula with real longitudinal studies.

5.1 Labor Pain Study (Continuous Outcome Case)

Davis^[10] introduced a study on labor pain where women in labor were randomly assigned to pain medication group and placebo arms. At 30 minutes intervals, the self-reported amount of pain was marked on a 100 mm line, where 0 = no pain and 100 = extreme pain. The maximum number of measurements for each woman was $m = 6$, but there were numerous missing values at later measurement times with monotone missing pattern. A simple approach to such study objective may be to estimate and compare the slopes of pain scores over time in two treatment groups. In this study, the outcome variable is continuous. Suppose that we want to design a new study on labor pain based on the data reported by Davis^[10]. As in the original study, we assume monotone missing. In this study, the measurement times

were equispaced, so that we set $t_j = j - 1$ ($j = 1, \dots, 6$) for convenience. From the data, we obtain $\sigma^2 = 815.84$. Suppose we want to detect a difference of σ in mean pain score between two groups at t_6 . So, we project $d = \sigma/(t_6 - t_1) = 5.71$ in a new study. We consider a balanced randomization, i.e. $r_1 = r_2 = 1/2$. Also, from the data, the proportion of observed measurements are

$$(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, \delta_6) = (1, .90, .78, .67, .54, .41).$$

From these results, we obtain $\tau = 2.02$ and $s^2 = 11.42$.

Suppose that we want to detect a difference of $d = 5.71$ with 80% of power ($z_{1-\beta} = 0.84$) using a two-sided $\alpha = .05$ ($z_{1-\alpha/2} = 1.96$) test. Under CS, we obtain $\rho = .64$ and $c = -3.13$ from the data, so that we have $v = 815.84 \times (11.42 - 3.13)/11.42^2 = 0.0635$. Hence, from (4), the required sample size is calculated as

$$n = \left\lceil \frac{0.0635 \times (1.96 + 0.84)^2}{5.71^2} \right\rceil + 1 = 50.$$

where $[x]$ is the largest integer not exceeding x .

Under AR(1), we obtain from the data $\rho = .80$ and $c = 2.31$, so that the required sample size for detecting $d = 5.71$ with 80% of power using a two-sided $\alpha = .05$ test is given as $n = 83$. The sample size under AR(1) is larger than that under CS, by about 66%, in this example.

5.2 GENISOS (Binary Outcome Case)

As stated in Introduction, GENISOS is an observational study. Suppose that we want to develop a new clinical trial to examine the effect of a new drug in preventing the occurrence of pulmonary fibrosis in subjects with scleroderma based on the observations from the observational study. The parameter values specified below for sample size calculation are approximated by the estimates from the current data set of GENISOS.

We want to estimate the sample size for the new clinical trial using $\alpha = .05$ and $1 - \beta = .8$. As in GENISOS, presence or absence of pulmonary fibrosis will be assessed at baseline, and at months 6, 12, 18, 24 and 30. Since the measurement times are equidistant, we set $t_j = j - 1$ ($j = 1, \dots, 6$) for the $m = 6$ time points. The within-group correlation structure of the repeated measurements conforms to AR(1) with the adjacent correlation equal to $\rho = .8$, that is, $\rho_{jj'} = .8^{|j-j'|}$. We consider assigning equal number of scleroderma patients in each of two groups, i.e. $r_1 = r_2 = 1/2$.

Approximately 75% of scleroderma patients do not have pulmonary fibrosis at the baseline in the ongoing GENISOS. We project that the proportion of subjects without pulmonary fibrosis is 75% at baseline, i.e. $p_{1,1} = .75$, and 50% at 30 months, i.e. $p_{1,6} = .50$, in a placebo group. We assume that a new therapy will prevent or delay further

occurrence of pulmonary fibrosis. That is, the proportion of subjects without pulmonary fibrosis will remain 75% during 30-month study in a new therapy group, i.e. $p_{2,1} = p_{2,6} = .75$. From these values and (5), we obtain

$$b_1 = \frac{g(.5) - g(.75)}{5 - 0} = -0.220,$$

and $a_1 = g(.75) = 1.099$. Similarly, we obtain $(a_2, b_2) = (1.099, 0)$, so that $d = 0 - (-0.220) = 0.220$. By (1), the probabilities of no pulmonary fibrosis at the 6 time points are obtained as $(.750, .707, .659, .608, .555, .500)$ for the placebo group, and $(.750, .750, .750, .750, .750, .750)$ for the treatment group.

The proportions of observed measurements are expected to be

$$(\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, \delta_6) = (1, .95, .90, .85, .80, .75).$$

Suppose that we expect independent missing. Then, we obtain $\delta_{jj'}$ from the specified δ_j values using $\delta_{jj'} = \delta_j \delta_{j'}$. Now we have all the parameter values required, and obtain $v_1 = 0.305$ and $v_2 = 0.353$. Finally, from (3), we obtain

$$n = \left\lceil \frac{(1.96 + 0.84)^2 (0.305 / 0.5 + 0.353 / 0.5)}{0.220^2} \right\rceil + 1 = 215.$$

If we assume monotone missing ($\delta_{jj'} = \delta_{j \vee j'}$), we obtain $v_1 = 0.324$, $v_2 = 0.308$ and $n = 229$.

Generalizability Probability in Clinical Research

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

This entry evaluates the generalizability of clinical results observed from a clinical trial by means of a sensitivity analysis with respect to changes in mean and standard deviation of the primary clinical endpoints of the study.

INTRODUCTION

For marketing approval of a new drug product, the U.S. Food and Drug Administration^[1] (FDA) requires that at least two adequate and well-controlled clinical trials be conducted to provide substantial evidence regarding the effectiveness and safety of the drug product under investigation. The purpose of requiring at least two clinical studies is not only to assure the reproducibility, but also to provide valuable information regarding *generalizability*. Generalizability refers to whether the clinical results can be generalized to other similar patient populations within the same region (e.g., the United States, Europe, or Asia-Pacific countries) or from region to region. When the sponsor of a newly developed or approved drug product is interested in getting the drug product into the marketplace from one region (e.g., where the drug product is developed and approved) to another region, differences in ethnic factors could alter the efficacy and safety of the drug product in the new region. The International Conference on Harmonization (ICH) recommends that a *bridging study* be conducted to generate a limited amount of clinical data in the new region in order to extrapolate the clinical data between the two regions.^[2]

In practice, it is important to determine whether a clinical trial that produced positive clinical results provides substantial evidence to assure generalizability of the clinical results from one region to another. This entry evaluates the generalizability of clinical results observed from a clinical trial by means of a sensitivity analysis with respect to changes in mean and standard deviation of the primary clinical endpoints of the study.

The next section introduces the concept of generalizability probability of a positive clinical result is introduced. Statistical methods for the evaluation of generalizability probability are discussed in “The Frequentist Approach” and “The Bayesian Approach.” Some applications in clinical research are provided in “Applications.”

GENERALIZABILITY

Consider the situation where the target patient population of the second clinical trial is similar but slightly different (e.g., because of the difference in ethnic factors) from the population of the first clinical trial. The difference in population may be reflected by the difference in mean, variance, or both mean and variance of the primary study endpoints. For example, the population means may be different when the patient populations in two trials are of different race. When a pediatric population is used for the first trial and adult patients or elderly patients are considered in the second trial, the population variance is likely to be different.

Shao and Chow^[3] define the reproducibility probability of the first trial as an estimated power of the second trial using the data from the first trial. The reproducibility probability, considered in Shao and Chow,^[3] with the population of the second trial slightly deviated from the population of the first trial is referred to as the generalizability probability. In the next section, we illustrate how to obtain generalizability probabilities in the case where the study design is a two-group parallel design with a common variance. Other cases can be similarly treated. More details can be found in Chow and Shao.^[4]

THE FREQUENTIST APPROACH

Consider the two-group parallel design. Let $\mu_1 - \mu_2$ be the population mean difference and σ^2 be the common population variance of the first trial. Suppose that in the second trial, the population mean difference is changed to $\mu_1 - \mu_2 + \varepsilon$ and the population variance is changed to $C^2\sigma^2$, where $C > 0$. If $|\mu_1 - \mu_2|/\sigma$ is the signal-to-noise ratio for the population difference in the first trial, then the signal-to-noise ratio for the population difference in the second trial is

$$\frac{|\mu_1 - \mu_2 + \varepsilon|}{C\sigma} = \frac{|\Delta(\mu_1 - \mu_2)|}{\sigma}$$

where

$$\Delta = \frac{1 + \varepsilon/(\mu_1 - \mu_2)}{C} \quad (1)$$

is a measure of change in the signal-to-noise ratio for the population difference. For most practical problems, $|\varepsilon| < |\mu_1 - \mu_2|$ and thus $\Delta > 0$. Suppose a total of $n = n_1 + n_2$ patients are randomly assigned to a treatment group and a control group, then, the power for the second trial is

$$1 - T_{n-2}(t_{0.975; n-2} | \Delta\theta) + T_{n-2}(-t_{0.975; n-2} | \Delta\theta)$$

where $T_{n-2}(\cdot | \Delta\theta)$ is the non-central t -distribution with $n - 2$ degrees of freedom and the non-centrality parameter $\Delta\theta$ and

$$\theta = \frac{\mu_1 - \mu_2}{\sigma \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (2)$$

Note that the power for the second trial is the same as the power for the first trial if and only if Δ in Eq. 1 equals 1. Define

$$T = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n - 2} \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}} \quad (3)$$

where $\bar{x}_i$'s and s_i^2 's are the sample means and variances, respectively, based on the data from the first trial. Then, the generalizability probability on the estimated power approach, as described in the entry *Reproducibility Probability in Clinical Research*, can be obtained with T replaced by ΔT , assuming that Δ is known, that is,

$$\hat{P}_\Delta = 1 - T_{n-2}(t_{0.975; n-2} | \Delta T) + T_{n-2}(-t_{0.975; n-2} | \Delta T)$$

The generalizability probability based on the confidence bound approach as outlined in the entry *Reproducibility Probability in Clinical Research*, is given by

$$\hat{P}_\Delta = 1 - T_{n-2}(t_{0.975; n-2} | \Delta\theta) + T_{n-2}(-t_{0.975; n-2} | \Delta\theta)$$

if $\theta > 0$ and $\hat{P}_{\Delta-} = 0$ if $\theta = 0$.

Values of $\hat{P}_\Delta$ and $\hat{P}_{\Delta-}$ can be obtained using Tables 2 and 3 in the entry of *Reproducibility Probability in Clinical Research* once n , Δ , and $T(x)$ are known. In practice, the value of Δ may be unknown. We may either consider a maximum possible value of $|\Delta|$ or a set of Δ values to carry out a sensitivity analysis.

THE BAYESIAN APPROACH

When σ^2 is unknown, consider the commonly used non-informative prior for σ^2 , i.e., $\pi(\sigma^2) = \sigma^{-2}$. Assume that the priors for μ_1, μ_2 , and σ^2 are independent. The posterior density for (δ, u^2) is

$$\pi(\delta | u^2, x) \pi(u^2 | x)$$

where

$$\begin{aligned} \delta &= \frac{\mu_1 - \mu_2}{\sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n - 2} \left(\frac{1}{n_1} + \frac{1}{n_2} \right)}} \\ u^2 &= \frac{(n - 2)\sigma^2}{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2} \\ \pi(\delta | u^2, x) &= \frac{1}{u} \phi\left(\frac{\delta - T(x)}{u}\right) \end{aligned}$$

ϕ is the density function of the standard normal distribution, T is given by (Eq. 3), and $\pi(u^2 | x) = f(u)$ with

$$f(u) = \left[\Gamma\left(\frac{n-2}{2}\right) \right]^{-1} \left(\frac{n-2}{2}\right)^{(n-2)/2} u^{-n} e^{-(n-2)/(2u^2)}.$$

Because θ in (Eq. 2) is equal to δu , the posterior mean of $p(\theta)$ is given by

$$\hat{P} = \int_0^\infty \left[\int_{-\infty}^\infty p\left(\frac{\delta}{u}\right) \phi\left(\frac{\delta - T(x)}{u}\right) d\delta \right] 2f(u) du \quad (4)$$

which is the so-called reproducibility probability under the Bayesian approach.

For the Bayesian approach with a known Δ given by Eq.1, the generalizability probability is given by

$$\hat{P}_\Delta = \int_0^\infty \left[\int_{-\infty}^\infty p\left(\frac{\Delta\delta}{u}\right) \phi\left(\frac{\delta - T(x)}{u}\right) d\delta \right] 2f(u) du \quad (5)$$

Table 5 in the entry of *Reproducibility Probability in Clinical Research* can be used to obtain the values of $\hat{P}_\Delta$ once n , Δ , and $T(x)$ are known. When Δ is unknown, the method considered above can be applied. Alternatively, we may consider the average of $\hat{P}_\Delta$ over a noninformative prior density $\pi(\Delta)$, that is,

$$\hat{P} = \int \hat{P}_\Delta \pi(\Delta) d\Delta$$

APPLICATIONS

In clinical development, after the investigational drug product has been shown to be effective and safe with respect

Table 1 Generalizability Probabilities and Sample Sizes for Clinical Trials in a New Population

Δ	The estimated power approach			The Bayesian approach		
	New sample size n^*			New sample size n^*		
	$\hat{P}_\Delta$	70% power	80% power	$\hat{P}_\Delta$	70% power	80% power
1.20	0.929	52	66	0.821	64	90
1.10	0.879	62	80	0.792	74	102
1.00	0.814	74	96	0.742	86	118
0.95	0.774	84	106	0.711	98	128
0.90	0.728	92	118	0.680	104	140
0.85	0.680	104	132	0.645	114	154
0.80	0.625	116	150	0.610	128	170
0.75	0.571	132	170	0.562	144	190

to a target patient population (e.g., adults), it is often of interest to study how likely the clinical result is reproducible in a similar but slightly different patient population (e.g., elderly patient population with the same disease under study or a patient population with different ethnic factors). This information is useful in regulatory submission or supplement new drug application (e.g., when generalizing the clinical results from adults to elderly patient population) and regulatory evaluation for bridging studies (e.g., when generalizing clinical results from Caucasian to Asian patient population). Detailed information regarding bridging studies can be found in ICH.^[2]

An Example

A double-blind randomized trial was conducted in patients with schizophrenia for comparing the efficacy of a test drug with a standard therapy. A total of 104 chronic schizophrenic patients participated in this study. Patients were randomly assigned to receive the treatment of the test drug or the standard therapy for at least one year, where the test drug group has 56 patients and the standard therapy group has 48 patients. The primary clinical endpoint of this trial was the total score of Positive and Negative Symptom Scales (PANSS). No significant differences in demographics and baseline characteristics were observed for baseline comparability.

Mean changes from baseline in total PANSS for the test drug and the standard therapy are $\bar{x}_1 = -3.51$ and $\bar{x}_2 = 1.41$, respectively, with $s_1^2 = 76.1$ and $s_2^2 = 74.9$. The difference $\mu_1 - \mu_2$ is estimated by $\bar{x}_1 - \bar{x}_2 = -4.92$ and is considered to be statistically significant with $T = -2.88$, a p -value of 0.004, and a reproducibility probability of 0.814 under the estimated power approach or 0.742 under the Bayesian approach.

The sponsor of this trial would like to evaluate the probability for reproducing the clinical result in a different population where Δ , the change in the signal-to-noise ratio, ranges from 0.75 to 1.2. The generalizability probabilities are given in Table 1 (because $|T| < 4$ the confidence bound

approach is not considered). In this example, $|T|$ is not very large and thus a clinical trial is necessary to evaluate in the new population. The generalizability probability can be used to determine the sample size n^* for such a clinical trial. The results are given in Table 1. For example, if $\Delta = 0.9$ and the desired power (reproducibility probability) is 80%, then $n^* = 118$ under the estimated power approach and 140 under the Bayesian approach; if the desired power (reproducibility probability) is 70%, then $n^* = 92$ under the estimated power approach and 104 under the Bayesian approach. A sample size smaller than that of the original trial is allowed if $\Delta \geq 1$; that is, the new population is less variable.

The sample sizes n^* in Table 1 are obtained as follows. Under the estimated power approach,

$$n^* = \left(\frac{T^*}{\Delta T} \right)^2 \left/ \left(\frac{1}{4n_1} + \frac{1}{4n_2} \right) \right.$$

where T^* is the value obtained from Table 2 of the entry *Reproducibility Probability in Clinical Research* for which the reproducibility probability has the desired level (e.g., 70% or 80%). Under the Bayesian approach, for each given Δ , we first compute the value T_Δ^* , at which the reproducibility probability has the desired level, and then use

$$n^* = \left(\frac{T_\Delta^*}{T} \right)^2 \left/ \left(\frac{1}{4n_1} + \frac{1}{4n_2} \right) \right.$$

CONCLUSION

In clinical research, it is important to determine whether the observed clinical results can be generalized from a patient population to another similar but slightly different patient population within the same region or from region to region. The assessment of generalizability probability using the frequentist approach or Bayesian approach is

helpful. The sensitivity analysis of generalizability probability is useful for determining whether a bridging clinical study is necessary from one region to another for regulatory review/approval of the drug product under investigation.

Abstract

The Generalized Estimating Equation method is an inferential procedure concerning the marginal mean of a multivariate outcome through regression models. This entry presents various test statistics to discuss the application of the GEE.

INTRODUCTION

The Generalized Estimating Equation (GEE,^[1,2]) method is an inferential procedure concerning the marginal mean of a multivariate outcome through regression models. The GEE method is based on assumptions regarding the first two moments, rather than the full distribution of an outcome vector. Since its introduction, GEE has been very popular, receiving more than 3,000 citations in the literature. Before the GEE era, regression models for multivariate outcomes, especially for non-normal outcomes, had no unifying approach and had been in limited use. While the classical linear model was extended naturally by generalized linear models (e.g., Ref. [3]) to outcomes arising from an exponential family distributions using various non-linear link functions, an analogous extension for linear models of multivariate normal outcomes to broader types of outcomes was not available mainly due to a lack of a rich class of multivariate distributions. Liang and Zeger^[1] cleverly circumvented this dilemma by borrowing the idea of quasi-likelihood,^[4] and presented GEE as a multivariate version of generalized linear models. Instead of making a full distributional assumption, GEE makes assumptions only on the mean and variance of an outcome as in quasi-likelihood models. In this sense, GEE can be viewed as a multivariate extension of the quasi-likelihood method. A technical distinction between the quasi-likelihood model and GEE is that the quasi-likelihood model does not allow nuisance parameters, except for the constant scale factor for the variance, whereas GEE does.

be zero is called the *estimating function*. A simple example of an estimating equation for the mean μ of random variable Y with a sample of n observations is:

$$\sum_{i=1}^n (Y_i - \mu) = 0.$$

This estimating equation gives the sample mean as the solution. Another well-known estimating equation is the normal equation that gives the Ordinary Least Squares Estimate as the solution. The score equation that yields maximum likelihood estimate as a solution is another example of an estimating equation. All the estimating functions mentioned above share the common characteristic of having zero expectation. For example,

$$E \left\{ \sum_{i=1}^n (Y_i - \mu) \right\} = n\mu - n\mu = 0.$$

Also, all of the estimators mentioned above are consistent. We show later that having zero expectation is key to proving consistency of the resulting estimator. We say that an estimating equation is *unbiased* if the corresponding estimating function has zero expectation. The Generalized Estimating Equation (GEE) is an unbiased *estimating equation* which has the form of a *generalized*, or modified, likelihood equation of a GLM.

Generalized Estimating Equations

Let $Y_i = (Y_{i1}, Y_{i2}, Y_{i3}, \dots, Y_{in_i})^T$ ($i = 1, 2, \dots, K$) be a vector of outcomes for subject i , and $X_i = (X_{i1}^T, X_{i2}^T, \dots, X_{in_i}^T)$ be a $p \times n_i$ covariate matrix where X_{ij} is a $1 \times p$ vector of covariates. Conditioning on X_i , the mean of Y is denoted by $E(Y_i | X_i) = \mu_i$, where $\mu_i = (\mu_{i1}, \mu_{i2}, \dots, \mu_{in_i})^T$. Y_i could represent measurements taken at n_i different occasions, or

NOTATION AND DEFINITION

Estimating Equations

An equation which yields an estimator as a solution is called an *estimating equation*, and the function equated to

time points, for subject i . While elements in Y_i may be correlated, $Y_1, Y_2, \dots, Y_K$ are independent vectors. The mean of Y_{ij} is

$$E(Y_{ij} | X_{ij}) = \mu_{ij} = g^{-1}(X_{ij}\beta),$$

where $g(\cdot)$ is a link function which relates the linear predictor $X_{ij}\beta$ to the mean μ_{ij} , and β is an unknown parameter of interest. For example, for binary outcomes using the logit link function,

$$\log \frac{\mu_{ij}}{1 - \mu_{ij}} = X_{ij}\beta,$$

the link function is $g(a) = \log \frac{a}{1-a}$. The parameter of interest β has interpretation of log odds ratio. We denote the variance of Y_{ij} by $v_{ij}(\mu_{ij})/\phi$, where ϕ is a scalar dispersion parameter. For example, if Y_{ij} is binary, $E(Y_{ij}) = \mu_{ij}$, $v_{ij}(\mu_{ij}) = \mu_{ij}(1 - \mu_{ij})$, and $\phi = 1$. If Y_{ij} is distributed univariate normal with mean μ_{ij} and variance (σ^2), then $v_{ij}(\mu_{ij}) = 1$, and $\phi = 1/\sigma^2$.

We assume the variance-covariance matrix of a random vector Y_i has the form:

$$V_i = A_i(\mu_i)^{1/2} R_i(\alpha) A_i(\mu_i)^{1/2} / \phi,$$

where A_i is a $n_i \times n_i$ diagonal matrix with the j^{th} diagonal element $v_{ij}(\mu_{ij})$, and $R_i(\alpha)$ is a correlation matrix. The GEE is defined as

$$U(\beta, \alpha) = \sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} (Y_i - \mu_i) = 0, \quad (1)$$

If α is known, the estimate of β , say $\hat{\beta}$, can be obtained by solving Eq. (1). The estimating function $U(\beta, \alpha)$ has a comparable form to the score function of a Generalized Linear Model (GLM). In fact, if $R_i = I_i$, where I_i is $n_i \times n_i$ identity matrix, the estimating function is identical to the score function of a GLM. However, it should be emphasized that specifying $R_i = I_i$ is not equivalent to assuming independence among $(Y_{i1}, Y_{i2}, Y_{i3}, \dots, Y_{in_i})$. This point will be revisited in the Working Correlation Section. The fundamental difference is that the estimating function $U(\beta, \alpha)$ is constructed, and is not derived from any target function to be maximized, whereas the score function is the derivative of the log-likelihood.

ASYMPTOTIC PROPERTIES

For any estimating equation to yield a consistent estimate it should be constructed to have zero expectation. This property is key to proving consistency and asymptotic normality of $\hat{\beta}$. To understand the proof heuristically, first consider the case in which α is known. Observe that

$$U(\hat{\beta}, \alpha) = 0.$$

Then, we can write

$$U(\hat{\beta}, \alpha) = 0 = U(\beta, \alpha) + \frac{\partial U(\beta, \alpha)}{\partial \beta^T} \bigg|_{\beta=\beta^*} (\hat{\beta} - \beta_0),$$

where $|\hat{\beta} - \beta^*| < |\hat{\beta} - \beta_0|$. This leads to

$$(\hat{\beta} - \beta_0) = \frac{\partial U(\beta, \alpha)}{\partial \beta^T} \bigg|_{\beta=\beta^*}^{-1} U(\beta_0, \alpha).$$

Denoting $E\left(\frac{\partial U(\beta, \alpha)}{\partial \beta^T}\right)$ by $W_0(\beta, \alpha)$, we have

$$W_0(\beta, \alpha) = \sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} \frac{\partial \mu_i}{\partial \beta^T}.$$

It can be shown that $\frac{\partial U(\beta, \alpha)}{\partial \beta^T} \bigg|_{\beta=\beta^*}$ converges to $W_0(\beta_0, \alpha)$. Then we have

$$(\hat{\beta} - \beta_0) \approx W_0(\beta_0, \alpha)^{-1} \{U(\beta_0, \alpha)\}. \quad (2)$$

Since $U(\beta_0, \alpha)$ is a sum of random vectors with mean zero and finite variance, by the central limit theorem, $U(\beta_0, \alpha)$ is distributed as multivariate normal. Then, Eq. (2) shows that $(\hat{\beta} - \beta_0)$ is a linear combination of random vectors from a multivariate normal distribution. Therefore $(\hat{\beta} - \beta_0)$ itself is distributed as multivariate normal, and we may write

$$\sqrt{K}(\hat{\beta} - \beta_0) \sim N_p(0, KV_{\hat{\beta}}),$$

where

$$V_{\hat{\beta}} = W_0(\beta_0, \alpha)^{-1} \text{Var}\{U(\beta_0, \alpha)\} W_0(\beta_0, \alpha)^{-1}$$

WORKING CORRELATION

Before we further discuss the variance of $U(\beta_0, \alpha)$, we need to revisit the correlation $R_i(\alpha)$. Zeger and Liang called it the “working correlation” to reflect the fact that R does not have to be the true correlation. If $R_i(\alpha)$ is not the true correlation but a specified “working” correlation, V_i is not the true variance of Y_i but only a specified variance, i.e. $E(Y_i - \mu_i)(Y_i - \mu_i)^T \neq V_i$. Let the variance of $U(\beta_0, \alpha)$ be $W_1(\beta_0, \alpha)$. Then

$$\begin{aligned} W_1(\beta_0, \alpha) &= \text{Var} \left(\sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} (Y_i - \mu_i) \right) \\ &= E \left(\sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} (Y_i - \mu_i) (Y_i - \mu_i)^T V_i^{-1} \frac{\partial \mu_i}{\partial \beta^T} \right). \end{aligned}$$

If $R(\alpha)$ is correctly specified, V_i is the correctly specified variance, i.e., $E(Y_i - \mu_i)(Y_i - \mu_i)^T = V_i$. Then the right-hand side becomes

$$\sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} E(Y_i - \mu_i)(Y_i - \mu_i)^T V_i^{-1} \frac{\partial \mu_i}{\partial \beta^T} = \sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} \frac{\partial \mu_i}{\partial \beta^T},$$

resulting in $W_i = W_0$. Even when R is misspecified, the variance $U(\beta_0, \alpha), W_1(\beta_0, \alpha)$, can be consistently estimated empirically by $\hat{W}_1$, that is

$$\sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} (Y_i - \mu_i)(Y_i - \mu_i)^T V_i^{-1} \frac{\partial \mu_i}{\partial \beta^T},$$

evaluated at $\beta = \hat{\beta}$. Then the variance of $\hat{\beta}$ is of ‘sandwich’ form, $W_0^{-1} W_1 W_0^{-1}$, and can be consistently estimated by

$$\hat{V}_{\hat{\beta}} = \hat{W}_0^{-1} \hat{W}_1 \hat{W}_0^{-1}.$$

Even when the correlation structure R is misspecified, this sandwich variance estimate is consistent for $V_{\hat{\beta}}$, and thus enables us to draw correct inferences. Misspecified correlation structure does not affect the consistency of $\hat{\beta}$ and $\hat{V}_{\hat{\beta}}$.

Since we can draw the correct inference even when we misspecify the working correlation structure R_i , we can intentionally choose $R_i = I_i$, although we disbelieve that Y_{ij} ’s are independent. In the case of a binary outcome with logit link, solving a GEE with $R_i = I_i$ is equivalent to fitting a logistic regression model for correlated Y_{ij} ’s as if all Y_{ij} ’s are independent. The GEE estimate in this case maximizes a product of Bernoulli distributions, which is not the true likelihood function, because Y_{ij} ’s are correlated. The above results show that the ordinary logistic regression parameter estimate is consistent even when Y_{ij} ’s are correlated, but that the correct variance estimate is $\hat{W}_0^{-1} \hat{W}_1 \hat{W}_0^{-1}$, not the usual variance estimate ($\hat{W}_0^{-1}$) for independent binary outcomes.

Alternatively the sandwich variance can be estimated by the Jackknife method. Let $\hat{\beta}_{-i}$ be the GEE estimate obtained after deleting the i^{th} independent unit or cluster. The Jackknife variance V_J ,

$$V_J = \sum_{i=1}^K (\hat{\beta}_{-i} - \hat{\beta})(\hat{\beta}_{-i} - \hat{\beta})^T,$$

can consistently estimate the sandwich variance $W_0^{-1} W_1 W_0^{-1}$. Use of the Jackknife variance to estimate a sandwich variance is discussed in Ziegler,^[5] and Lipsitz, Dear and Zhao.^[6]

Efficiency

If the misspecified working correlation yields consistent estimates, what is the advantage of correctly specifying the correlation structure? The answer is efficiency. Let the correct correlation matrix be R_i^* and corresponding W_0 be W_0^* . The variance of $\hat{\beta}$ is smallest when R is correctly

specified, and has the form W_0^{*-1} , whereas the variance of $\hat{\beta}$ is $W_0^{-1} W_1 W_0^{-1}$ when $R_i \neq R_i^*$. If the dimension of β is one, the asymptotic relative efficiency (ARE) of the estimator with misspecified correlation structure is

$$\text{ARE} = W_0^{-1} W_1 W_0^{-1} W_0^*.$$

By applying the maximization and minimization theorem of quadratic forms, we can see that the ARE of a linear combination of $\hat{\beta}$ lies between the largest and smallest eigenvalues of $W_0^{-1} W_1 W_0^{-1} W_0^*$. Rotnitzky and Jewell^[7] provide the upper and lower bounds for efficiency under some special correlation structures. Efficiency of GEE when $R(\alpha)$ is misspecified has been examined analytically^[8] and by simulation.^[9,10]

Estimation of Correlation α

When $R(\alpha)$ is a function of unknown parameter α , we need to estimate α . Note that α is assumed common to all i . The correlation matrix could be different depending on the unit, but should be completely determined by α , a vector of a relatively small dimension, for the asymptotic results of $\hat{\beta}$ to hold.

Estimators of α sometimes involve another unknown parameter ϕ . Then unknown ϕ can be replaced by a consistent estimate of ϕ , which can be obtained by

$$\hat{\phi}^{-1} = \sum_{i=1}^K \sum_{j=1}^{n_i} \frac{(Y_{ij} - \mu_{ij})}{\sqrt{v(\mu_{ij})}} \bigg/ \sum_{i=1}^K n_i.$$

Liang and Zeger^[1] have provided several examples of correlation structures. One simple example is the intraclass correlation matrix.

$$R_i(\alpha) = \begin{pmatrix} 1, \alpha, \alpha, \dots, \alpha \\ \alpha, 1, \alpha, \dots, \alpha \\ \alpha, \alpha, 1, \dots, \alpha \\ \dots, \dots, \dots, \dots, \dots \\ \alpha, \alpha, \alpha, \dots, 1 \end{pmatrix}.$$

In this case, the estimate of α can be obtained as

$$\hat{\alpha} = \left\{ \sum_{i=1}^K \sum_{j>k} \frac{(Y_{ij} - \mu_{ij})(Y_{ik} - \mu_{ik})}{\sqrt{v(\mu_{ij})} \sqrt{v(\mu_{ik})}} \right\} \hat{\phi} \bigg/ \sum_{i=1}^K n_i(n_i - 1)/2.$$

Another example is auto-regressive of order 1 (AR-1), where the $(j, k)^{\text{th}}$ element of matrix $R_i(\alpha)$ is $\alpha^{|j-k|}$:

$$R_i(\alpha) = \begin{pmatrix} 1, \alpha, \alpha^2, \dots, \alpha^{n_i-1} \\ \alpha, 1, \alpha, \dots, \alpha^{n_i-2} \\ \alpha^2, \alpha, 1, \dots, \alpha^{n_i-3} \\ \dots, \dots, \dots, \dots, \dots \\ \alpha^{n_i-1}, \alpha^{n_i-2}, \alpha^{n_i-3}, \dots, 1 \end{pmatrix}.$$

In this case, α can be estimated as the regression coefficient in a regression model with zero intercept, $(Y_{ij} - \mu_{ij})/\sqrt{v(\mu_{ij})}$ as the dependent variable, and $(Y_{ij-1} - \mu_{ij-1})/\sqrt{v(\mu_{ij-1})}$ as the independent variable.

Muñoz et al.^[11] proposed a flexible family of correlation structures in which the $(j, k)^{\text{th}}$ element of matrix $R_i(\alpha)$ is $\alpha^{|j-k|^\delta}$. With an additional parameter δ , this family can express various types of correlation structures including AR-1 ($\delta = 1$) and intraclass correlation ($\delta = 0$).

When the number of sub-units is the same for all units ($n_i = n$ for all i), we can assume that $R_i(\alpha) = R(\alpha)$, and can estimate all $n(n-1)/2$ unknown parameters without specifying a particular structure:

$$\hat{R}(\alpha) = K^{-1} \sum_{i=1}^K \hat{A}_i^{-\frac{1}{2}} (Y_i - \hat{\mu}_i) (Y_i - \hat{\mu}_i)^T \hat{A}_i^{-\frac{1}{2}} / \hat{\phi}.$$

Note that the estimation of α depends on β , and in turn, the estimation of β depends on α . Each step should be alternated until both parameters converge. It turns out that estimating unknown α does not affect inference on β given some assumptions.^[11] A crucial assumption is that the estimate of α is $\sqrt{K}$ -consistent. To see why heuristically, first we write the estimating function as follows:

$$U(\beta, \hat{\alpha}(\beta)) = 0.$$

Taylor's expansion gives

$$U(\beta, \hat{\alpha}(\beta)) \approx U(\beta, \alpha_0(\beta)) + (\hat{\alpha} - \alpha_0)^T \frac{\partial U}{\partial \alpha}.$$

Denoting the j^{th} element of α by α_j , we have

$$\begin{aligned} \frac{\partial U}{\partial \alpha_j} &= \sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} \frac{\partial V_i^{-1}}{\partial \alpha_j} (Y_i - \mu_i) \\ &= \sum_{i=1}^K \frac{\partial \mu_i^T}{\partial \beta} V_i^{-1} \frac{\partial V_i^{-1}}{\partial \alpha_j} V_i^{-1} (Y_i - \mu_i) = O_p(K^{\frac{1}{2}}), \end{aligned}$$

because it is a sum of random vector with mean zero. With the condition $\sqrt{K}(\hat{\alpha} - \alpha_0) = O_p(1)$, we find

$$(\hat{\alpha} - \alpha_0)^T \frac{\partial U}{\partial \alpha} = O_p(1),$$

which is of smaller order than $U(\beta, \alpha_0(\beta))$. Since $U(\beta, \hat{\alpha}(\beta))$ is asymptotically equivalent to $U(\beta, \alpha_0(\beta))$, the inference about β can be drawn by ignoring the fact that α is estimated. Uncertainty added by $\hat{\alpha}$ replacing α is of small order and does not affect the asymptotic results of $\hat{\beta}$.

TEST STATISTICS

In likelihood theory, we can draw inference using three different, but related test statistics: Wald tests, Score tests,

and Likelihood ratio tests. Wald tests are based on the asymptotic normality of the maximum likelihood estimator. Score tests are based on the asymptotic normality of the score function evaluated at the null value. Likelihood ratio tests are based on the asymptotic chi square distribution of the difference of the log likelihoods evaluated for two nested models. Since the GEE is not derived from a likelihood function, the aforementioned three test statistics do not exist. However, we can construct similar test statistics. Consider a partition, $\beta^T = (\beta_1^T, \beta_2^T)$, where β_1 is the parameter of interest of length q and β_2 is a nuisance parameter with length $p - q$. We are interested in testing hypothesis $H_0: \beta_1 = \beta_{10}$.

Wald-Type Statistics

The Wald-type statistics can be formed by

$$T_w = (\hat{\beta}_1 - \beta_{10})^T \text{var}(\hat{\beta}_1)^{-1} (\hat{\beta}_1 - \beta_{10}),$$

where $\hat{\beta}_1$ is a $q \times 1$ sub-vector of the GEE estimate $\hat{\beta}$, and $\text{var}(\hat{\beta}_1)$ is a corresponding $q \times q$ sub-matrix of the sandwich variance $\hat{W}_0^{-1} \hat{W}_1 \hat{W}_0^{-1}$. The test statistic is asymptotically chi square distributed with q degrees of freedom.

Score-Type Statistics

For correlated binary outcomes, Lepkopolou, Moore and Ryan^[12] examined the score-type statistics for inference of GEE under the independent working correlation structure, i.e., $R = I$. The score-type statistics can be considered in the same way for general structure of $R(\alpha)$ and for other types of outcomes. Consider the partition of estimating function $U(\beta, \alpha) = \begin{pmatrix} U_1(\beta_1, \beta_2, \alpha) \\ U_2(\beta_1, \beta_2, \alpha) \end{pmatrix}$, where $U_1(\beta_{10}, \tilde{\beta}_2, \alpha)$ is a q -variate sub-vector of estimating function $U(\beta, \alpha)$ corresponding to β_1 . The Score-type statistics also can be formed by

$$T_s = U_1(\beta_{10}, \tilde{\beta}_2, \alpha)^T \text{var}\{U_1(\beta_{10}, \tilde{\beta}_2, \alpha)\}^{-1} U_1(\beta_{10}, \tilde{\beta}_2, \alpha),$$

where $\tilde{\beta}_2$ is the solution of $U(\beta_{10}, \beta_2, \alpha) = 0$, i.e., the GEE estimate of β_2 under the restriction $\beta_1 = \beta_{10}$. Consider a similar partition for matrices W_0 and W_1 :

$$\begin{aligned} W_0 &= E \begin{pmatrix} \frac{\partial U_1}{\partial \beta_1^T}, \frac{\partial U_1}{\partial \beta_2^T} \\ \frac{\partial U_2}{\partial \beta_1^T}, \frac{\partial U_2}{\partial \beta_2^T} \end{pmatrix} = \begin{pmatrix} D_{11}, D_{12} \\ D_{21}, D_{22} \end{pmatrix}, \text{ and} \\ W_1 &= \begin{pmatrix} M_{11}, M_{12} \\ M_{21}, M_{22} \end{pmatrix}. \end{aligned}$$

It can be easily verified that $D_{21} = D_{12}^T$ and $M_{21} = M_{12}^T$. To obtain the variance of $U(\beta_{10}, \tilde{\beta}_2, \alpha)$ we can consider the following expression:

$$U(\beta_{10}, \tilde{\beta}_2, \alpha) \approx U_1(\beta_{10}, \beta_{20}, \alpha) - D_{12} D_{22}^{-1} U_2(\beta_1, \beta_2, \alpha).$$

Then

$$\text{var}\{U(\beta_{10}, \tilde{\beta}_2, \alpha)\} = M_{11} + D_{12} D_{22}^{-1} M_{22} D_{22}^{-1} D_{21} - 2 D_{12} D_{22}^{-1} M_{21}.$$

The test statistic T_s is distributed as chi square with q degrees of freedom. Replacing α with $\tilde{\alpha}$ (the estimate of α under the null) does not affect the asymptotic distribution of the test statistic. One disadvantage of using T_s is that the computation of the score statistic requires a specialized program.

Likelihood Ratio-Type

When $R = I$, the GEE estimating function is the same as the score function of GLM, and the GEE estimate maximizes the function that is the likelihood function if the Y_{ij} 's are independent. Since the Y_{ij} 's are *not* independent, the maximized function by the GEE estimator is not the likelihood function. For example, when Y_{ij} is binary, the maximized function is

$$\sum_{i=1}^K \left(\sum_{j=1}^{n_i} Y_{ij} \log \left\{ \mu_{ij} / (1 - \mu_{ij}) \right\} - (1 - Y_{ij}) \log(1 - \mu_{ij}) \right).$$

In general, suppose that marginally Y_{ij} at the j^{th} occasion or time point arises from an exponential family distribution. Let the product of the densities of Y_{ij} 's be $L(\beta; Y)$. Although $L(\beta; Y)$ is not the likelihood function, we can form a likelihood ratio-like statistic for testing $\beta_1 = \beta_{10}$ in the presence of the nuisance parameter β_2 , and consider its asymptotic properties when the Y_{ij} 's are in fact correlated. Let the likelihood ratio-like statistic be T_L and

$$T_L = 2 \left\{ L(\hat{\beta}_1, \hat{\beta}_2) - L(\beta_{10}, \tilde{\beta}_2) \right\},$$

where $\tilde{\beta}_2$ is the maximizer of L under the restriction $\beta_1 = \beta_{10}$.

Rotnitzky and Jewell^[7] considered the distribution of T_L , when Y_{ij} 's are correlated. They showed that T_L can be expressed as a weighted sum of independent chi square variables with one degree of freedom. Denoting $\chi_1, \dots, \chi_q$ as q independent chi square random variables with one degree of freedom, they showed

$$T_L \approx \sum_{j=1}^q d_j \chi_j^2,$$

where $d_1 \geq d_2 \geq \dots \geq d_q$ are eigenvalues of $P \approx P_0^{-1} P_1$, where

$$P_0 = D_{11} - D_{12} D_{22}^{-1} D_{21}, \quad \text{and} \\ P_1 = M_{11} + D_{12} D_{22}^{-1} M_{22} D_{22}^{-1} D_{21} - 2 D_{12} D_{22}^{-1} M_{21},$$

where all sub-matrices D and M in P_0 and P_1 are evaluated at $\alpha = 0$. When there are no nuisance parameters, $P_0 = W_0$ and $P_1 = W_1$.

Rotnitzky and Jewell^[7] also derived the distributions of the "aïve" Wald and Score tests where statistics are formed as if all observations were independent. Those statistics are found to be asymptotically equivalent to T_L .

USING GEE WITH CAUTION

The GEE draws inference on the mean of Y given X . Although it is conditional on X , in the literature it is referred to as the marginal mean in the sense that it is the mean of an outcome at a single time point without conditioning on the other elements of the outcome vector. The GEE is the method to use when the interest is on the marginal mean. The interpretation of the regression parameters is also in terms of the marginal mean. Specifically, the regression coefficient β in GEE features *population average effects* that compare the mean outcome for a group of subjects in the population who have a specific value X , say x_1 versus another group who have $X = x_2$. On the other hand, one may be interested in *subject specific effects* that compare the mean outcome when a subject has a specific value $X = x_1$ vs. when the same subject has $X = x_2$.^[13] The GEE does not address subject-specific effects. Such inference can be drawn using mixed effects models. Several ways of extending GLM to mixed effects models are suggested.^[13–15]

Given that the main interest is in population average effects, one should note that the asymptotic properties of GEE depend on large K and fixed n_i . For studies with large n_i or small K , one may consider alternative methods. Even when K is large with fixed n_i , problems associated with specification of the working correlation structure may arise. For some working correlation structures such as m -dependence, there is a range of α that yields non-positive definite matrices. Users should make sure that the estimated correlation matrix is positive definite. A more fundamental problem is the lack of definition of the working correlation coefficient α .^[16] One of the assumptions used to derive the asymptotic properties of $\hat{\beta}$ is $\sqrt{K}$ -consistency of $\hat{\alpha}$. The problem is that α is not a true correlation, but merely a working correlation, and sometimes it is not clear what $\hat{\alpha}$ is estimating. Crowder^[16] examined this issue and cautioned that in some cases, α is subject to uncertainty of definition, leading to a breakdown of the asymptotic properties of $\hat{\beta}$. In the case of independent working correlation models, this problem can be avoided. Especially in the case of

canonical link function (e.g., logit link for binary; log link for Poisson; identity link for normal), the GEE estimates are guaranteed to exist. It is a good practice to fit an independent working correlation model first before fitting more complicated working correlation structures.

EXTENSIONS OF GEE

Various extensions of GEE have been proposed by many authors. Ziegler et al.^[17] gives an extensive annotated bibliography on GEE.

Joint Modeling

Prentice^[18] considered modeling not only the mean as a function of covariates, but also correlation as a function of covariates. The estimating equation for the correlation is stacked with the original GEE for β to form a joint estimating equation. Liang, Zeger and Qaqish^[19] modeled jointly the mean and the odds ratio between the repeated measurements, instead of correlation, and called it GEE2. Paik^[20] considered joint modeling of mean and scale parameter, ϕ . A joint modeling of mean, scale, and correlation parameter by separate link functions was proposed by Yan and Fine^[21] and later improved by Lee, Paik and Lee^[22] by employing the covariance structure of multivariate normal distribution. For multi-level multivariate data, for example, data with multiple measurements per each family member, correlation structure becomes complicated. In this case Lee, Paik and Lee^[23] proposed joint modeling of mean, scale, and canonical correlation. Instead of modeling pairwise correlation, they proposed to model canonical correlation which is maximal correlation between linear combinations of multiple measurements for two family members. Modelling aspects allow the canonical correlation to be expressed as a function of pair specific covariates.

A class of multivariate exponential family called partial exponential family is proposed by Zhao, Prentice, and Self,^[24] who have shown that the score function of the partial exponential family has the same form as GEE if the GEE variance matrix is correctly specified. However, partial exponential family distributions cannot be expressed in terms of (β, α, ϕ) , and iterative computation is required to translate (β, α, ϕ) , to the parameters in a partial exponential family. Nonetheless, mere existence of such family of distributions provides a basis of data generating mechanisms useful for research in GEE. Prentice and Zhao^[25] considered joint modeling using multivariate binary distribution that belongs to the partial exponential family.

Nonparametric GEE

Lin and Carroll^[26] developed nonparametric GEE to handle clustered data employing polynomial kernel smoothing.

Lin and Carroll^[27,28] extended their approach for the partial linear model, where the linear predictor is parametric for some covariates and non-parametric for others. They noted that their method requires either independent working correlation or an artificial under smoothing to guarantee the $\sqrt{K}$ -consistency of the slope. Although the original GEE is efficient with correctly specified within-subject correlation, their kernel GEE obtained higher efficiency with independent working correlation than with true correlation. Wang^[29] and Wang, Carroll, and Lin^[30] modified the Lin and Carroll's method by defining neighbors accounting for the correlation structure, and improved the efficiency. Chen and Jin^[31] proposed an alternative method having $\sqrt{K}$ -consistency for the regression estimator using "local" working correlation matrix which performs better than working independent correlation structure.

Missing Data

Another important issue is missing data. Note that GEE naturally handles varying numbers of sub-units in the independent unit. For example, varying numbers of repeated measurements across subjects possibly resulting from dropout is not an obstacle to fitting GEE models. However, it is valid only when the missingness probability does not depend on the outcome Y (called missing completely at random). If the probability of missingness depends on observed or on unobserved Y , the GEE estimate is not consistent. To fix this problem, Robins, Rotnitzky, and Zhao^[32] have proposed a weighted GEE in which each observation is weighted by the inverse of probability of observation. The authors also proposed a modified weighted GEE to improve the efficiency of the initially proposed weighted GEE. Paik^[33] has proposed imputed GEE where missing outcome is replaced with the estimates of the conditional expectation given observed data. Fitzmaurice et al.^[34] have examined the bias when the missingness mechanism is informative. Xie and Paik^[35,36] have proposed an imputation approach when covariates are missing. Lipsitz et al.^[37] have considered imputation approach for multivariate binary data using multivariate Gaussian model.

GENETIC APPLICATION OF GEE

One of the most popular applications of GEE has been in the field of quantitative genetics. In genetics, it is often of interest to investigate if sharing genes through familial relationship increases the risk of developing a disease. When the trait of interest was continuously measured, the interest would be to see if sharing genes through familial relationship produces a similar level for two quantitative traits from a relative pair. A multivariate outcome from family members is often to be analyzed, so the GEE has been used in the analysis along with likelihood-based modeling approach.

To examine whether or not there is any genetic effect on a trait, the correlation of the trait among family members can be compared with that among genetically unrelated individuals, after adjusting for other confounders. The joint modeling of mean, scale, and correlation parameters has been found to be useful in attacking this problem. Yan and Fine^[21] have illustrated their methods in the application of familial correlation analysis for a single trait, and Lee, Paik, and Lee,^[23] have done the same for multiple traits.

One of the most popular approaches is to implement a subject specific random genetic and environmental effect model. In this case, heritability, which is the ratio of the variance of random genetic effects given the expected proportions of sharing identity by descent (IBD) genes to the total variance of a trait, measures the genetic effect on the trait. Based on the random effect model, various approaches have been developed to locate genes by inferring a function of the variance of random genetic effects given the *locus specific* estimates of proportions of sharing IBD genes. One approach is to directly infer the variance component. Many authors applied joint modeling for GEE by Prentice and Zhao^[25] to estimate the locus specific genetic variance and compared the results with maximum likelihood estimates.^[38–40] Another approach is the Haseman-Elston regression^[41] where outcome is the squared differences in the trait values of relative pairs and independent variable is the estimates of the proportions of sharing IBD genes. Variance estimation and the Haseman-Elston regression approaches are shown to be framed in the context of GEE by Chen, Broman, and Liang.^[42,43]

COMPUTATION

The GEE regression estimates under the independent working correlation structure can be obtained by using any software that fits GLM. However, the variance reported by this software would be the diagonal elements of $\hat{W}_0^{-1}$. To compute the correct variance, we need to calculate $\hat{W}_1$ as well. Some software packages have routines to fit GEE and report the sandwich variance estimates. SAS (PROC GENMOD), Stata (XTGEE), and SUDAAN (PROC MULTILOG, PROC LOGISTIC and PROC REGRESS) are among the commercially available programs. SUDAAN also supports a jackknife variance estimator using independent working correlation. For review and comparison of those software, see Horton and Lipsitz.^[44] GEE is also available in S-PLUS(GEE or YAGS) or in R(GEE or GEEPACK).

Abstract

This entry provides a brief description of generalized test variables and generalized pivotal quantities and supplies application examples.

INTRODUCTION

Generalized test variables (GTVs) and generalized pivotal quantities (GPQs) were proposed by Tsui and Weerahandi,^[1] and Weerahandi,^[2] respectively. When the conventional frequenting methods fail to provide satisfactory solutions for hypothesis test or interval estimation about some complex parametric functions, GTVs and GPQs may serve as an easy tractable means of computing generalized p -values and generalized confidence intervals (GCI) for them. According to many simulation studies, the generalized inference often performs satisfactorily in the repeated sampling argument.

Generalized p -values and GCIs have been applied successfully to many biological studies such as occupational exposure limit estimation,^[3,4] population and individual bioequivalence,^[5] accuracy comparison with ROC curves,^[6,7] confidence limits about effect measures,^[8] tolerance intervals for linear models,^[9,10] growth curve estimation,^[11,12] common mean estimation for several normal populations,^[13,14] the means and variances of a bivariate log-normal distribution,^[15] and others. An in-depth review of these procedures and their applications was presented in the two textbooks by Weerahandi.^[16,17]

We introduce the concepts of generalized p -values and GCIs in the next section. We demonstrate the applications with ROC curve and tolerance interval inference in the section “Examples,” and we discuss some possible drawbacks of generalized inference in the section “Limitations.” Finally, a brief summary is given in the conclusion.

GENERALIZED p -VALUE AND GENERALIZED CONFIDENCE INTERVAL

Suppose that Y is a random sample whose distribution depends on a vector of unknown parameters $\zeta = (\theta, \eta)$,

where θ is a parameter of interest, and η is a vector of nuisance parameters. Let y be the observed value of Y . A random quantity $T = T(Y; y, \zeta)$ is said to be a GTV for θ if it satisfies the following three conditions:

- The distribution of T is free of nuisance parameters η .
- The observed value of T , say $t_{obs} = T(y; y, \zeta)$, does not depend on unknown parameters.
- For fixed y and η , $P[T \leq t | \theta]$ is monotonic in θ for all t .

A generalized extreme region for testing null hypothesis $H_0 : \theta \in \Theta_0$ versus alternative hypothesis $H_1 : \theta \in \Theta_1$ is defined as $C = \{Y : T(Y; y, \zeta) \geq t_{obs}\}$ such that small probabilities of C indicate evidence against the null hypothesis, where Θ_0 is some subset of the parameter space and Θ_1 is its complement. Then, a generalized p -value is defined as

$$p = \sup_{\theta \in \Theta_0} P[C | \theta].$$

For the test with a nominal significance level α , one typically rejects null hypothesis if $p < \alpha$. The exact distribution function of T is usually too complicated to derive; thus, the generalized p -value is often computed by Monte Carlo algorithm.

Similarly, a random quantity $R = R(Y; y, \zeta)$ is said to be a GPQ for θ if it satisfies the following two conditions:

- The distribution of R is free of unknown parameters.
- The observed value of R , say $r_{obs} = R(y; y, \zeta)$, does not depend on nuisance parameters η .

A GTV and a GPQ for θ can be easily transformed to be each other, because both of them must fulfill two identical conditions. A GCI for θ is usually obtained from appropriate percentiles of a sampling distribution of R based on Monte-Carlo algorithms.

EXAMPLES

The Area Under the ROC Curve

Suppose that Y and X are the two variables from a diagnostic device for a diseased patient and a non-diseased patient, respectively. Let θ be the area under the ROC curve (AUC), measuring the accuracy of the diagnostic device. Then, it can be verified that $\theta = P(Y > X)$.^[18] Under the normality assumption that $Y \sim N(\mu_Y, \sigma_Y^2)$ and $X \sim N(\mu_X, \sigma_X^2)$,

$$\theta = \Phi \left(\frac{\mu_Y - \mu_X}{\sqrt{\sigma_Y^2 + \sigma_X^2}} \right).$$

We now show how to find a GTV for θ . Suppose $\bar{Y}$ and S_Y^2 are the sample mean and sample variance for the diseased with n samples, and $\bar{X}$ and S_X^2 are those for the non-diseased with m samples. Thus, $Z = [(\bar{Y} - \bar{X}) - (\mu_Y - \mu_X)] / \sqrt{\sigma_Y^2/n + \sigma_X^2/m} \sim N(0,1)$, $U = (n-1)S_Y^2/\sigma_Y^2 \sim \chi_{n-1}^2$, and $V = (m-1)S_X^2/\sigma_X^2 \sim \chi_{m-1}^2$. We have GPQs for σ_Y^2 and σ_X^2 as $R_{\sigma_Y^2} = (n-1)S_Y^2/U$ and $R_{\sigma_X^2} = (m-1)S_X^2/V$, respectively. Also, a GPQ for $\mu_Y - \mu_X$ and is $R_{\mu_Y - \mu_X} = \bar{y} - \bar{x} - Z \sqrt{R_{\sigma_Y^2}/n + R_{\sigma_X^2}/m}$, where $s_Y^2, s_X^2, \bar{y}$ and $\bar{x}$ are the observed values of $S_Y^2, S_X^2, \bar{Y}$ and $\bar{X}$, respectively. Consequently, we obtain a GTV for θ given by

$$T = T(\bar{Y}, \bar{X}, S_Y^2, S_X^2; \bar{y}, \bar{x}, s_Y^2, s_X^2, \theta) = R_\theta - \theta,$$

where

$$R_\theta = \Phi \left(\frac{R_{\mu_Y - \mu_X}}{\sqrt{R_{\sigma_Y^2} + R_{\sigma_X^2}}} \right).$$

It is easy to verify R_θ is a GPQ for θ , and the distribution function of T is a monotonic function in θ , thus T is a GTV for θ . For testing $H_0: \theta \leq \theta_0$ versus $H_1: \theta > \theta_0$, where θ_0 is a pre-specified value, one can generate a sampling distribution of R_θ by mutually independent $R_{\sigma_Y^2}, R_{\sigma_X^2}$ and $R_{\mu_Y - \mu_X}$. The required generalized p -value consequently is estimated by the proportion of the realized values of R_θ that are greater than or equal to θ_0 .

Tolerance Intervals for Balanced Linear Models

Let F denote the cumulative distribution for a random variable W . An interval $[L(Y), U(Y)]$, based on a random sample Y , is said to be a two-sided β -content, γ -confidence tolerance interval, denoted by (β, γ) -tolerance interval, for F if

$$Pr\{[F(U(Y)) - F(L(Y))] \geq \beta\} = \gamma.$$

Thus, one can state with confidence coefficient γ that at least a proportion β of the population modeled by F is contained in the interval $[L, U]$. Similarly, one-sided tolerance limits can be defined.

Suppose that $W \sim N(\theta, T^2)$, where $T^2 = \sum_{i=1}^q h_i \sigma_i^2$. Also, h_i are known constants and each σ_i^2 denotes a linear combination of the variance components in a balanced linear model. Thus, mutually independent observable statistics $G, S_1^2, S_2^2, \dots, S_q^2$ are available such that

- $G \sim N(\theta, \sigma^2)$, where $\sigma^2 = \sum_{i=1}^q c_i \sigma_i^2$ and c_i are known constants.
- $f_i S_i^2 / \sigma_i^2 \sim \chi_{f_i}^2$, for $i = 1, 2, \dots, q$.

It is easy to show that an upper (β, γ) -tolerance limit for W is in fact a γ -confidence upper bound for $\delta = \theta + z_\beta \tau$. Because an exact γ -confidence upper bound for δ is generally unavailable, an upper generalized γ -confidence bound for δ , denoted by $R_{\delta, \gamma}$, is thus a useful surrogate. Let g denote the observed value of G and $s_1^2, s_2^2, \dots, s_q^2$ denote the observed values of $S_1^2, S_2^2, \dots, S_q^2$. We thus have $Z = (G - \theta)/\sigma \sim N(0,1)$ and $U_i = f_i S_i^2 / \sigma_i^2 \sim \chi_{f_i}^2$. Define

$$\begin{aligned} R_\theta &= g - Z \sqrt{\max \left\{ 0, \sum_{i=1}^q \frac{c_i f_i s_i^2}{U_i} \right\}} \\ &= g - \left(\frac{G - \theta}{\sigma} \right) \sqrt{\max \left\{ 0, \sum_{i=1}^q \frac{c_i \sigma_i^2 s_i^2}{S_i^2} \right\}} \end{aligned}$$

and

$$R_T = \sqrt{\max \left\{ 0, \sum_{i=1}^q \frac{h_i f_i s_i^2}{U_i} \right\}} = \sqrt{\max \left\{ 0, \sum_{i=1}^q \frac{h_i \sigma_i^2 s_i^2}{S_i^2} \right\}}.$$

It can easily be verified that R_θ and R_T are GPQs for θ and T respectively. So a GPQ for δ is given by

$$R_\delta = R_\theta + z_\beta R_T.$$

Similarly, the desired $R_{\delta, \gamma}$ for an upper (β, γ) -tolerance limit can be simply obtained from a Monte-Carlo algorithm.

Limitations

Stimulation studies have shown that generalized inference can be successfully applicable to many practical situations. More interestingly, Hannig^[19] provided the connection between generalized inference and fiducial inference. Also, Hannig et al.^[20] proposed that GCIs asymptotically maintain the target coverage level for a large class of parametric problems. These imply that the GCIs are no worse asymptotically than the intervals based on asymptotic normality of the estimators of the parametric functions of interest.

However, the generalized inference still suffers from some possible limitations. First, the choice of a GTV or GPQ for a parametric function can be non-unique. In addition, there is no guarantee that all of them enjoy good performance in the repeated sampling argument.^[19,20] Second, generalized inference is usually made on a limited number of continuous distributions like normal and log-normal distributions. There is no much work has been studied about it for a parametric function of a discrete distribution. Third, it still needs further theoretical investigation on the sufficient conditions that generalized inference can be a workable tool in the frequenting argument, particularly in the small sample situations. For the most cases according to generalized inference, one still needs an intensive simulation study to verify their performance. Certainly, a simulation study cannot cover all parameter spaces.

CONCLUSION

Even though generalized inference has been successfully applicable to a wide range of statistical problems and many problems of practical importance. A useful procedure of finding a GTV or GPQ for a parametric function if it exists can be found in.^[16] However, the user should be careful to make inference based on it.

Abstract

This entry describes the basic concepts of and commonly used methods in genetic mapping [linkage and linkage disequilibrium (LD) analysis] of quantitative trait loci (QTL).

INTRODUCTION

Genetic mapping of human traits (phenotypes) aims to identify chromosomal regions that contain genes affecting traits of interest and especially genes that affect human susceptibility to particular diseases. There are many single-gene diseases (e.g., Huntington's disease) that are caused by a change of a single gene. There are also many polygenic diseases resulting from the combined action of alleles of more than one gene (e.g., heart disease and diabetes). A great deal of attention has been focused on identifying disease genes in order that they may be used for disease diagnoses, personalized treatment, and the prediction of treatment outcomes.

Pharmacogenetics can aid biopharmaceutical research and development in many ways. First, it is applied in diagnosis of disease. An important example is prenatal genetic screening, such as amniocentesis for the Down syndrome and newborn genetic screening for inherited metabolic disorders. Second, it is applied in drug efficacy prediction. A typical clinical trial would have a third or more patients who do not respond to the test drug. By identifying the genes that are associated with drug response, it is possible to improve drug response rates in clinical trials by selecting targeted patient populations. See Ref. [1] for a list of genes that have been significantly associated with drug response. Third, similar to predicting drug efficacy, it is applied in side effects prediction of a drug (common side effects in clinical trials and/or rare side effects of marketed drug). Fourth, it would be applied in market expansion in the sense of identifying patients who are currently unsuited to the drug but potentially responsive to the drug when dosage or formula is selected based on their genotypes. Finally, clinical, genetic, and molecular phenotypes can be integrated to identify drug targets.

In this article we will describe the basic concepts of and commonly used methods in genetic mapping [linkage and linkage disequilibrium (LD) analysis] of quantitative trait loci (QTL). Interested readers can go through the references cited here or elsewhere for more information on mapping QTL. Classical linkage analysis is described in section "Classical Linkage Analysis," and it can be used to construct a genetic map according to the distances between marker pairs. The idea of linkage and LD analysis is to scan the genome to detect the correlation between phenotype and the markers. Two commonly used methods used for linkage and LD analysis, regression and variance-component methods, are described in section "Mapping QTL." Section "Genetics of Complex Diseases: The Endophenotype Approach" describes some of our work on mapping QTL of neurological and psychiatric disorders. The last section is devoted to discussion.

CLASSICAL LINKAGE ANALYSIS

Chromosomes are long strands of deoxyribonucleic acid (DNA) made up of four bases or nucleotides: A (adenine), C (cytosine), T (thymine), and G (guanine). Each individual has 23 pairs of chromosomes. Each chromosome pair has a paternal homologue (a copy carried by the sperm) and a maternal homologue (a copy carried by the egg). Genes are basic units of inheritance (short segments of DNA) and act as if linearly arranged at field places (loci) on a chromosome transmitted in the gametes from parent to offspring. It is now believed that the human genome has around 20,000–25,000 genes. A genetic marker is a segment of DNA with an identifiable physical location on a chromosome and whose inheritance can be followed. A marker can be a gene or a group of genes, or it can be

some section of DNA with no known function. One type of marker is a Short Tandem Repeat, which is a sequence of DNA nucleotides (dinucleotides, trinucleotides, etc.) that varies among individuals in terms of how many times the sequence is repeated (AT, ATAT, ATATAT, etc.). A more recently developed marker is the single nucleotide polymorphism (SNP) in which individuals differ in a single nucleotide at that location (e.g., some individuals have the sequence ATAGCTA, while others have the sequence ATAGGTA). Markers are selected that vary among individuals, i.e., the selected markers are informative. Because DNA segments that lie near each other on a chromosome tend to be inherited together, markers are often used as indirect ways of tracking the inheritance pattern of a gene that has not yet been identified but whose approximate location is known. An allele is one of several alternative forms of a marker occupying the same locus on a particular chromosome. Genotype data at a marker refer to the maternal and paternal alleles at the marker.

The process of forming germ cells is called meiosis. During meiosis, the chromosome pairs are split and the maternal and paternal homologues recombine (crossover), forming two new homologues. This random shuffling of genetic material is called recombination. Every germ cell (sperm or egg) contains one homologue from each of the 23 chromosome pairs. During fertilization, a sperm and an egg combine, and the paternal and maternal homologues form a full chromosomal set. As a result of crossover, each offspring will carry genes from all four grandparents. If no crossover had occurred, the offspring would have only inherited genes from two grandparents.

The genetic distance between two markers is defined as the expected number of crossovers between them. Note that genetic distance is not a measure of the physical distance between the two markers on a chromosome. Haldane's model of recombination is that crossover occurs according to a Poisson process, leading to the mapping function

$$\theta = (1 - e^{-2x})/2$$

where θ is the recombination probability between two markers and x is the genetic distance in Morgans (expected number of crossovers) between the two markers. See Ref. [2] for other mapping functions. With all distances between marker pairs being computed, a genetic map can be constructed to show the relative locations of the markers along the chromosome. Genetic maps are used in linkage analysis to identify markers for disease traits. New techniques have produced dense maps with more markers (e.g., SNPs), and hence enable fine mapping of disease genes.

MAPPING QTL

A qualitative trait is expressed qualitatively, which means that the phenotype (what you see) falls into different

categories (e.g., blood types) and is a clear representation of its genotype. A quantitative trait shows continuous variation (e.g., height or blood pressure) because the trait is under the influence of many genes. Most of these genes have a small effect on the total phenotype value. In addition to the genetic effects associated with the quantitative trait, the phenotype is directly influenced by environmental factors. This results in the observed phenotypic variation appearing continuous in nature. This is further complicated by gene–gene interactions and gene–environment interactions. The observed phenotype for a quantitative trait is the sum of all genetic effects across all involved genes and environmental effects.

Mapping of qualitative and QTL (genes) is used to study the relation between a phenotypic value and one or more genetic markers. A large correlation between a phenotype value and a marker genotype indicates that the marker is close to a gene that influences the phenotype. Various statistical models and methods have been developed to study this correlation. Some methods are based on pedigree data (linkage analysis) while other methods are based on population and pedigree data (association methods). Combined linkage and association methods have improved statistical power. We will focus on statistical methods for mapping QTL, which are more complicated than mapping qualitative trait loci. These methods are also applicable or can be adapted to map qualitative trait loci.

Heritability

The concept of heritability was introduced to quantify the level of predictability of passage of a biologically interesting phenotype from parent to offspring.^[3] The phenotype is seen as a function of environment and genotype. Assuming additive and independent effects of genes and environment (a simplified model), phenotypic variance (V_p) of a trait in a population may be expressed by one component of genetic variance (V_G) and one of environmental variance (V_E), so that $V_p = V_G + V_E$.

Heritability measures how the genetic contribution to a trait might vary in a population, and the heritability coefficient, H^2 , is given by the ratio of the total genetic variance to the phenotypic variance: $H^2 = V_G/V_p$. This is the broad heritability. Another measure, the narrow heritability, is only based on the additive genetic variation. We will discuss additive genetic variance and dominant genetic variance in the next section when we describe the variance-component model. The heritability can be used to predict the effects of searching for genes. It is easier to detect genes determining a trait if heritability of the trait is stronger. But heritability analysis does not provide any information about the locations of the contributing genes. This is the purpose of linkage/LD analysis.

The phenotypic variance (V_p) is observed, but the genetic variance (V_G) has to be estimated. If genotype data are available, marker-based methods can be employed to

estimate heritability.^[4,5] Note that heritability can be estimated without knowing genotypes. To estimate heritability from phenotypes without genotype data, one would need to make additional assumptions or focus on specific pairs of relatives so that phenotype variance is not completely described by environmental effects. A popular approach is to use twins^[6] and assume equal environmental effects.

Linkage Analysis

As QTL are unknown, linkage analysis studies the coinheritance of phenotypes and marker genotypes within families. One expects relatives who have similar phenotypes to have similar genotypes at marker loci close to genetic loci that influence the trait, while markers at distant loci behave stochastically according to the rules of Mendelian inheritance. We will review two of the most commonly used methods and their extensions: Haseman–Elston regression^[7] and variance-component model.^[4,8]

Two genes are identical by descent (IBD) if one is a copy of the other or if both are physical copies of the same ancestral gene. Thus a parent and a child always share one allele IBD at each locus. Two siblings can share 0, 1, or 2 alleles IBD at each locus with probabilities 1/4, 1/2, and 1/4, respectively. For a distant pair of relatives in a complex pedigree, it is impossible to enumerate all the possibilities of allele sharing and all the breeding types, to calculate the allele sharing IBD probabilities between the pair. It is even more difficult for multipoint analysis. Statistical methods have been developed to estimate the allele sharing IBD probabilities between any pair of a pedigree.^[4,9,10] Some methods are deterministic while most are stochastic (Monte Carlo techniques).

If linkage exists between a trait locus and a marker, then alleles sharing IBD at the two loci are correlated. The Haseman and Elston^[7] method (H–E method) is derived for sib pairs and for regressing the squared sib-pair trait phenotype difference on the proportion of alleles the sibs are estimated to share IBD at a marker locus. Let y_{1j} and y_{2j} be the normalized phenotype values of the j th sib pair such that the population mean is zero. Let π_j be the estimated proportion of alleles the j th sib pair shared IBD at a marker locus. The slope β from the regression line

$$(y_{1j} - y_{2j})^2 = \beta_0 + \pi_j \beta + \varepsilon_j$$

indicates whether a linkage exists between the trait locus and the marker locus. The intercept β_0 is of no particular interest, and ε_j is the residual. The slope β is negatively proportional to the genetic part of the phenotype variance. If β is negative then there exists linkage between a trait locus and the marker locus, because it correlates similarity at a trait locus with similarity at the marker locus (sharing more alleles IBD makes the phenotype difference between the sib pair smaller). For each marker on a genetic map,

one can carry out the regression and find out which markers are statistically significantly linked to the trait loci. The trait loci are close to these chromosome locations. With more dense maps available because of advanced technology, one can do two sweeps to save computational time: The first sweep is on a relatively sparse map to find the rough locations of the trait loci, and the second sweep is on all the available markers in a neighborhood of those rough locations. Note that this is a multitest problem, but the p -values are not adjusted.

Extensions of the H–E method have been developed to increase statistical power. Wright^[11] pointed out that sib-pair QTL linkage information is not fully utilized by considering only phenotype differences of sib pairs. Further information can be obtained from phenotype sums of sib pairs. Sham and Purcell^[12] proposed a combined H–E method. This method regresses a linear combination of $(y_{1j} + y_{2j})^2$ and $(y_{1j} - y_{2j})^2$ on π_j , the estimated proportion of alleles shared IBD at a marker locus by sib pairs. Elston et al.^[13] introduced an improved H–E method which regresses the products of the sib phenotypes, $y_{1j}y_{2j}$, on the estimated proportion of alleles shared IBD. Olson and Wijsman^[14] extended the H–E method for use with general pedigrees, considering $(y_{1j} - y_{2j})^2$ for all relative pairs. These H–E methods typically use the Wald statistic based on the SE from ordinary least squares.

For the variance-component model,^[4,8] the phenotype values of a pedigree are assumed to follow a multivariate normal distribution. Let $\mathbf{Y}_i = (y_{i1}, y_{i2}, \dots)'$ be the phenotypes of the i th pedigree. If there are n trait loci influencing the trait, then the variance-component model can be written as

$$y_{ik} = \mu + x_{ik}\beta + \sum_{j=1}^n \gamma_{ikj} + \varepsilon_{ik} \quad (1)$$

where μ is the grand mean, x_{ik} is a vector of covariates (e.g., age, gender), β represents fixed effects corresponding to the covariates, γ_{ikj} is the effect of the j th QTL, and ε_{ik} represents a random environmental deviation. Assume γ_{ikj} and ε_{ik} are uncorrelated random variables with mean 0 and variance σ_j^2 and σ_ε^2 , respectively. With both additive and dominant effects, $\sigma_j^2 = \sigma_{aj}^2 + \sigma_{dj}^2$, where σ_{aj}^2 is the additive genetic variance and σ_{dj}^2 is the dominant genetic variance. The variance of y_{ik} is

$$\sigma_y^2 = \sum_{j=1}^n \sigma_j^2 + \sigma_\varepsilon^2$$

and the phenotype covariance between a pair of relatives indexed by k and m is

$$\begin{aligned} \text{COV}(y_{ik}, y_{im}) &= E[(y_{ik} - \mu)(y_{im} - \mu)] \\ &= \sum_{j=1}^n [\pi_{kmj} \sigma_{aj}^2 + \kappa_{kmj} \sigma_{dj}^2] \end{aligned}$$

where π_{kmj} is the proportion of alleles shared IBD at the j th QTL by the relative pair and κ_{kmj} is the j th QTL-specific probability of the pair of relatives sharing two alleles IBD. Both π_{kmj} and κ_{kmj} can be estimated from genetic marker data.

To search for the QTL that influence the phenotype values, one would focus on one QTL at a time. If we focus on the j th QTL, then model (1) can be written as

$$y_{ik} = \mu + x_{ik}\beta + \gamma_{ikj} + g_{ik} + \varepsilon_{ik}$$

where g_{ik} represents the random genetic effect by all QTL other than the j th QTL. The covariance between a pair of relatives indexed by k and m is then

$$\text{COV}(y_{ik}, y_{im}) = \pi_{kmj}\sigma_{aj}^2 + \kappa_{kmj}\sigma_{dj}^2 + 2\phi_{km}\sigma_g^2 + \delta_{km}\sigma_d^2 \quad (2)$$

where $\phi_{km} = E[\pi_{kmj}]/2$ is the expected kinship coefficient over the genome and $\delta_{km} = E[\kappa_{kmj}]$ is the expected probability of sharing two alleles IBD.

The variance-component model uses likelihood ratios to test significance of each marker. Let $\Delta_i = Y_i - (\mu, \mu, \dots)' - [(x_{i1}, x_{i2}, \dots)\beta]'$ be the centered phenotype values of the i th pedigree and Ω_i be its covariance matrix at the j th QTL with elements given by Eq. (2). Assume Y_i follows a multivariate normal distribution. The log-likelihood of the i th pedigree with t individuals at the j th QTL is

$$\ln L_i(\mu, \beta, \sigma_{aj}^2, \sigma_{dj}^2, \sigma_g^2, \sigma_d^2 | Y_i, (x_{i1}, x_{i2}, \dots)) = -\frac{t}{2} \ln(2\pi) - \frac{1}{2} \ln(|\Omega_i|) - \frac{1}{2} \Delta_i' \Omega_i^{-1} \Delta_i \quad (3)$$

If there are N pedigrees, then the log-likelihood of all pedigrees is simply the sum of the log-likelihood for each pedigree. Likelihood estimation results in consistent parameter estimates even when multivariate normality assumption is violated.^[8] Simulations confirm the consistency of variance-component estimates of genetic effect size.^[15]

LOD Score

If the j th QTL in formula (2) does not contribute to the trait under study, then Eq. (2) becomes a reduced model

$$\text{COV}(y_{ik}, y_{im}) = 2\phi_{km}\sigma_g^2 + \delta_{km}\sigma_d^2 \quad (4)$$

and the log-likelihood (3) is reduced to

$$\ln L_i(\mu, \beta, \sigma_g^2, \sigma_d^2 | Y_i, (x_{i1}, x_{i2}, \dots)) = -\frac{t}{2} \ln(2\pi) - \frac{1}{2} \ln(|\Omega_i^r|) - \frac{1}{2} \Delta_i' (\Omega_i^r)^{-1} \Delta_i \quad (5)$$

where Ω_i^r is a covariance matrix at the j th QTL with elements given by Eq. (4). If there are N pedigrees, then the log-likelihood of all pedigrees for the reduced model is the sum of the log-likelihood for each pedigree.

The hypothesis of no effect of j th QTL can be tested by likelihood ratio test. To this end, we calculate the logarithm of the odds (to the base 10) (LOD) score

$$\text{LOD} = -\log_{10} \frac{\hat{L}_r}{\hat{L}}$$

Here $\hat{L}$ is the likelihood of full model (3) with parameters estimated by maximum-likelihood method, and $\hat{L}_r$ is the likelihood of reduced model (5) with parameters estimated by maximum-likelihood method.

It is typical to interpret a LOD score above 3 as evidence of linkage. Roughly speaking, a LOD score of 3 corresponds to a p -value of 0.0001. This is much more stringent than the usual significance level of 0.05 and is for controlling the false positive rate when performing multiple tests. To find a chromosome location (marker) close to a QTL, we need to scan the genome at many markers.

IBD Estimation

Both H-E and variance-component methods rely on IBD sharing probabilities between relatives within a pedigree, but it is impossible to obtain IBD sharing probabilities directly at QTL. Many statistical methods have been developed to estimate IBD allele sharing at QTL from genetic marker data. The idea is that if a QTL is close to a marker, then recombination between the QTL and the marker is rare. Consequently, IBD allele sharing is almost identical at the QTL and the marker. More accurate estimate of IBD allele sharing at a QTL can be obtained by using multiple markers in the vicinity of the QTL.

Davis et al.^[16] proposed an algorithm to calculate IBD probabilities for complicated pedigrees when there is no missing genetic marker information. The method of Fulker, Cherny, and Garton^[17] is a multipoint estimation of IBD allele sharing for sib pairs, and Almasy and Blangero^[4] extend this multipoint approach to arbitrary pairs in a pedigree. Jung, Fan, and Jin^[18] estimate IBD allele sharing at a QTL by a linear combination of IBD allele sharing at multiple markers in the vicinity of the QTL.

LD and Fine Mapping

Linkage analysis is a pedigree-based method that relies on the phenomena of recombination (each chromosome that an offspring receives from a parent consists of segments derived from both grandparents). In practice, one can only obtain DNA samples from a few generations of a pedigree. It is unlikely to observe recombination events between two closely linked markers from pedigree data. Therefore linkage analysis has limited resolution and is usually not able to localize genes within 1.0 cM.^[19]

As a complement to linkage analysis, association mapping or LD mapping is a population-based analysis and offers an approach for obtaining more precise location of

disease genes—the so-called fine mapping. LD refers to the statistical dependence of alleles at different loci, i.e., $P(AB) \neq P(A)P(B)$. A frequently used measure is the correlation coefficient Δ^2 .^[20] Usually fine mapping uses dense markers of SNP. A SNP gives rise to two alleles. Consider two biallelic loci with alleles A and a at one locus and alleles B and b at the other, where labeling is arbitrary. Let π_A , π_a , π_B , and π_b be the allele frequencies, and let π_{AB} , π_{aB} , π_{Ab} , and π_{ab} be the four haplotype frequencies. Then

$$\Delta^2 = (\pi_{AB} - \pi_A \pi_B)^2 / (\pi_A \pi_a \pi_B \pi_b)$$

A Chi-square test can be constructed to test the hypothesis of independence between marker pairs.^[19] Note that linkage always implies association, but association (correlation) between two markers does not necessarily imply linkage, because the correlation could be because of population stratification. So association mapping has high resolution but with a high false positive rate. One can use linkage analysis to scan the genome for markers affecting a trait, and then use association mapping in the neighborhoods of those markers for precise locations of the QTL.

For mapping QTL one has to detect correlation between markers and quantitative traits. Luo, Tao, and Zeng^[21] proposed a likelihood analysis method to estimate LD between a marker and a QTL using unrelated individuals in a natural population. With this maximum-likelihood analysis, the QTL genotypes are considered as missing data and an expectation-maximization algorithm is applied to infer the genotype information. Then QTL allele frequencies, LD between the QTL and the marker under consideration, and QTL effects are estimated simultaneously. Thus the association analysis does not require pedigree data, though pedigree information can be used to avoid bias because of population stratification and to have additional power.

Association studies can also be regarded as identity by state (IBS) analysis. Two alleles are IBS if they are of the same type but are not necessarily pure copies. Two individuals sharing alleles IBS at a marker are not necessarily sharing alleles IBD. The regression and variance-component methods can be applied to both pedigree data and population data using allele sharing IBS. LD between an SNP and a QTL can be achieved by incorporation of the mean effects model as a measured covariate^[22–25] with likelihood approach. Consider a QTL with alleles A and a that contribute to the phenotype y . There are three genotypes, $G = AA, Aa$, and aa , at the SNP. Because the contribution of the SNP to trait y depends on the genotype G , the mean of the trait $E(y)$ will depend on the genotype G as well. Assuming additive effects of SNP alleles, the mean of the trait can be modeled as

$$E(y|G) = \mu + \beta N_A$$

where N_A is the number of A alleles corresponding to genotype G , and β is the regression coefficient describing the

strength of the influence of the genotype on the trait.^[25] It is possible to test whether the phenotypic mean differs between individuals with different genotypes by comparing the likelihood of a model with genotype-specific trait means to that of a model with equal means for all genotypes.

Combined Linkage and LD Analysis

Family pedigree data can be used for both linkage and LD analysis, and population data can be used in LD analysis. Combined linkage and LD mapping would allow the use of both pedigree and population data, reduce the false positive linkage because of the use of pedigree allele sharing IBD information, and at the same time allow the use of more dense maps (e.g., SNPs) for fine mapping because of LD analysis. Combined linkage and LD analysis will have more power in detecting QTL.

Almasy et al.^[26] proposed an approach to use allele sharing IBS information between unrelated individuals to augment the linkage information obtained from allele sharing IBD among relatives. This is an extension of the variance-component method for linkage analysis of Almasy and Blangero.^[4] Fulker et al.^[23] proposed a combined linkage and LD analysis using sib pairs. Their likelihood approach models linkage parameters in the covariance structure while they model LD parameters on the means of the phenotype. The idea is that population stratification will influence sib-pair means of the phenotype but not sib-pair differences. So modeling the gene effect differently for pair means and pair differences will reduce spurious LD. Fan and Xiong^[24] proposed a two-point method based on variance-component models. In their model, linkage information is contained in the variance-covariance matrix based on family data, and the LD information is contained in the mean parameter based on both family pedigree and population data.

Software

The literature on linkage and LD analysis is very rich, and software has been developed for QTL mapping in abundance. The webpage <http://www.nslj-genetics.org/soft/> has a comprehensive list of software for genetic linkage analysis, marker mapping, LD mapping, and pedigree drawing. Selecting an analysis method and software depends on the experimental design (twin study, sib-pair data, general pedigree, natural population, etc.).

Regression and variance-component methods are commonly used for QTL mapping. The H-E regression method using sib-pair data is available in GENEHUNTER, and the regression method is extended to general pedigree data in Multipoint Engine for Rapid Likelihood Inference (MERLIN). The variance-component method is available in GENEHUNTER, MERLIN, and Sequential Oligogenic Linkage Analysis Routines (SOLAR). We have been using

SOLAR^[4] for combined linkage and LD mapping of QTL of psychiatric disorders. Variance-component methods are more powerful than regression methods but with more restricted assumptions such as normality of the phenotypes. SOLAR is robust in phenotype distribution and it has a *t*-distribution option.

GENETICS OF COMPLEX DISEASES: THE ENDPHENOTYPE APPROACH

Linkage analysis techniques have been successfully utilized to locate genes of rare Mendelian diseases; however, these methods have had only marginal success in locating genes associated with more common complex (non-Mendelian) disorders such as neurological and psychiatric diseases. Some of the reasons for these difficulties include the disorders resulting from small effects of many genes (polygenic disorders), incomplete or low penetrance, clinical and genetic heterogeneity, the presence of phenocopies, and diagnosis uncertainty. However, some recent successes have resulted from the use of methods, which efficiently utilize full pedigree structures in extended pedigrees, and which employ QTL underlying disease phenotypes (endophenotypes or intermediate phenotypes).^[27] These quantitative biological markers serve as covariates that correlate with the main trait of interest (diagnosis) and serve to better define that trait or its underlying genetic mechanism.^[28] Endophenotypes therefore represent the genetic liability of the disorder among non-affected relatives of affected individuals.

To qualify as an endophenotype of a disorder, the trait in question must meet a number of criteria:

1. The trait must be present in affected individuals and correlate with diagnosis and severity of disease or age of onset.
2. The trait must reflect susceptibility and not be the consequence of transient states.
3. The trait must be present in unaffected relatives of affected controls with levels significantly higher than in random controls.
4. The trait must be heritable.

Here we provide a brief overview of work being undertaken as part of the Collaborative Study on the Genetics of Alcoholism (COGA) project. The overarching goal of COGA is to identify genes that affect the susceptibility to develop alcohol dependence and related phenotypes. The gene mapping strategy employed by COGA integrates quantitative endophenotypes derived from human electroencephalogram (EEG) recording along with extensive psychiatric diagnostic tools. This methodology has resulted in the identification of several susceptibility genes, two of which are summarized here.

The COGA

Alcoholism is a complex disease influenced by underlying biological susceptibility factors, by environmental factors, and by complex interactions among genes and between genes and the environment. Since its inception COGA has carefully ascertained and assessed a large sample of densely affected alcoholic families, a sample of less densely affected families, and a sample of comparison families unselected for psychiatric status. This task was conducted to obtain highly informative families and to obtain reasonable power for genetic analyses. A unique approach taken by COGA is the adoption of neuroelectric measures as quantitative endophenotypes to the study of genetic risk for the development of alcoholism and related disorders. Inherent in this approach is the ability to study neuroelectric phenomenon as phenotypes of cognition, which has the potential to elucidate the genetic underpinnings of human brain oscillations.

COGA has reported several important linkage findings for the major clinical phenotype, alcohol dependence, as well as for related clinical features of alcohol dependence such as smoking, depression, suicidal behavior, and conduct disorder.^[29,30] A number of the significant COGA linkage findings for alcoholism have been consequent to highly significant linkage findings using neuroelectric endophenotypes.^[31,32] These significant linkage findings have been followed up with LD studies to identify specific genes within these regions of linkage.

The Utility of EEG as a Quantitative Endophenotype

Recording brain electrical activity using scalp electrodes provides a non-invasive, sensitive measure of brain function in humans. These neuroelectric phenomena may be recorded during the continuous EEG when the subject is at rest, or one may record the time-specific event-related potentials (ERPs) and event-related oscillations (EROs) during specific cognitive tasks. These neuroelectric phenomena represent important measurable correlates of human information processing and cognition. They represent traits less complex and more proximal to gene function than either diagnostic labels or traditional cognitive measures do.^[33] The human brain response, as measured by recording and measuring EEG features, may be utilized as phenotypes of cognition, and as valuable tools for the understanding of some complex genetic disorders.^[34]

Two examples of the use of neuroelectric endophenotypes from the COGA project are summarized below. These neuroelectric measures were obtained using two types of EEG experiment: eyes closed resting EEG and the visual oddball ERP. The neuroelectric endophenotypes used in the examples have been shown to adhere

to the endophenotype qualification criteria outlined above. The first example uses resting EEG β band power which has been shown in several studies to have increased power in alcoholics, offspring of alcoholics, and high-risk individuals, particularly during the resting condition.^[34] Using twin studies, resting EEG β power has been found to be highly heritable with estimates between 80% and 90%.^[35] The second example uses measures derived from the P300 wave evoked during the visual oddball event-related experiment; these measures were designed to quantify the EROs underlying the P300 potential. Several studies have demonstrated that reduced P300 amplitude is found in alcoholics and their offspring, and is associated with the risk for alcoholism^[34,36,37] suggesting that the P300 is a useful endophenotype indexing familial risk for alcoholism. A P300 amplitude heritability estimate of 60% has been established through a meta-analysis of five P300 twin studies.^[38]

Example 1: Spontaneous β Band (16–20 Hz) EEG Oscillations During the Eyes Closed Resting State

EEG recordings were obtained with non-invasive scalp electrodes in the individuals who were awake but eyes closed. The filtered, artifact-free data were transformed into horizontal bipolar derivations. EEG absolute power between 3 and 28 Hz were subdivided into θ (3.0–7.0 Hz), $\alpha 1$ (7.5–9.0 Hz), $\alpha 2$ (9.5–12.0 Hz), $\beta 1$ (12.5–16.0 Hz), $\beta 2$ (16.5–20.0 Hz), and $\beta 3$ (20.5–28.0 Hz). A singular value decomposition procedure^[39] was utilized to obtain phenotypic data for each of the six EEG power bands.

Using the EEG- $\beta 2$ phenotypic data, a variance-component linkage analysis^[4] revealed significant linkage on a region of chromosome 4p, with a LOD score of 5 in alcoholic families (Fig. 1). Furthermore, a microsatellite marker in *GABRB1* in the center of this region showed LD with EEG- $\beta 2$. A combined linkage/LD analysis^[26] using this marker resulted in an increased LOD score of 6.5, which equates to an association p -value of 0.004.^[31] The estimated disequilibrium parameter ($\rho_d = 0.57$) indicated LD between the *GABRB1* microsatellite marker and the functional QTL. In addition, a novel non-parametric multipoint linkage technique also gave strong evidence for linkage in this region ($P < 1.0 \times 10^{-6}$) using the same EEG- $\beta 2$ phenotype.^[40]

These results implicated the GABA_A gene cluster as containing the causative functional genetic variants influencing the phenotype. This cluster includes the *GABRA2*, *GABRA4*, *GABRG1*, and *GABRB1* genes. The actions of GABA_A receptors are believed to be a fundamental requirement for the generation of high-frequency EEG oscillations (β and γ band), and blockade of these receptors has been observed to result in the loss of synchronization of these oscillations.^[41] Also, a number of important effects of alcohol are mediated by GABA transmission,^[42] making

Fig. 2 Illustration of the ERO phenotypes used in the genetic analysis of visual oddball data. Traditional grand averaged evoked response potentials are depicted in (A) corresponding to target condition data for a frontal (Fz) and posterior (Pz) electrode. The P300 event is observed as a positive-going deflection starting approximately 300 msec after the target stimulus presentation. Time-frequency representations (TFR) of the target condition data (calculated using the S-transform) are depicted in (B) for the Fz electrode and (C) for the Pz electrode. These representations are obtained by averaging the instantaneous amplitude of the individual trial TFR data, and hence incorporate both stimulus phase locked and nonphase locked energy. Mean values calculated from individual subjects within time-frequency windows of interest were used as phenotypes in the genetic analysis. The inset head plots in (B) and (C) illustrate the distribution of these phenotypic measures across the head averaged within the θ and δ frequency bands and during the “P300” poststimulus time window (300–700 msec). (View this art in color at <http://www.informaworld.com>)

observed in the head plot insets of Fig. 2B and C that the θ band ERO component of the P300 response has a fronto-central distribution on the head, whereas the δ component shows a more posterior distribution.

A genome-wide variance-component linkage analysis of frontal channel θ band ERO data revealed significant linkage (LOD = 3.5) on chromosome 7q at 171 cM (Fig. 3). A cholinergic muscarinic receptor gene, *CHRM2*, resides near this locus and is a likely candidate to account for these linkage findings. The results of subsequent association analysis of the phenotype using SNPs genotyped within and flanking the *CHRM2* gene are provided in Table 1.

Table 1 Genetic Association *p*-Values (Uncorrected) for the Frontal Electrode Visual Oddball θ Phenotype with *CHRM2* SNPs

<i>CHRM2</i> SNPs (allele frequencies)	Measured genotype association		Gamete competition
	Additive model— <i>p</i> -value	Dominant model— <i>p</i> -value	<i>p</i> -Value
rs1824024 (G: 0.33/T: 0.67)	0.0008***	0.09	0.007**
rs2350786 (A: 0.29/G: 0.71)	0.015*	0.11	0.02*
rs8191992 (A: 0.41/T: 0.59)	0.53	0.48	0.14
rs1378650 (C: 0.58/T: 0.42)	0.2	0.68	0.015*

These results were obtained using a Caucasian-only subset of the original data to curtail possible stratification effects. The additive model measured genotype results (implemented in SOLAR) were obtained using a population-based measured genotype SNP model in which AA SNP genotypes are coded as −1, Aa genotypes are coded as 0, and aa genotypes are coded as 1. The dominant model measured genotype results were obtained using a population-based measured genotype SNP model in which AA and aa SNP genotypes are coded as 1 and Aa SNP genotypes are coded as 0. Age, gender, age-squared, and age by gender were included in the measured genotype models as fixed effects on the phenotype trait mean. The gamete competition association method (implemented in MENDEL) tests whether transmission of an allele is correlated with higher (or lower) trait values in the recipient of the allele. Age and gender effects on the quantitative traits were removed by linear regression prior to the gamete competition analysis.

CONCLUSIONS

A few of the current relevant issues regarding genetic mapping of complex traits will now be discussed. One important question is how large a sample size is required to have a reasonable power to detect linkage/association if it exists. Pfeiffer and Gail^[51] calculated sample size for population- and family-based case-control association studies using additive scores for various choices of marker allele frequencies (Table 2 in Ref. [51]). Olson and Wijsman^[52] considered several designs and sample size requirements in detecting LD. The simulation of Ekström^[53] shows that the LOD score with 300 sib pairs is much smaller than the LOD score with 100 four-sib nuclear families without information on parental genotypes using variance-component linkage models. This confirms that a smaller number of larger pedigrees are more informative than a larger number of smaller pedigrees for linkage analysis. Multipoint analysis gives increased power over single-point analysis to map QTL. Similarly, multitrait analysis provides accurate estimates of QTL positions.^[54] Multitrait methods use multivariate statistical models (multitrait single-point and multitrait multipoint). The methods described in section “Mapping QTL” can be extended to multitrait cases.

Sample size depends on required level of statistical significance, required power, design, test statistic to be used, and factors such as magnitude of effect. For linkage and LD analysis, such factors include the proportion of variance explained by QTL, gene action, marker heterozygosity, and density. The closed-form formula for sample size calculations is available in the literature. For the variance-component model, the generalized likelihood ratio test has a central Chi-square distribution under null hypothesis (no genetic component in phenotype variance) and has a non-central Chi-square distribution under alternative hypothesis. For sibship data and the variance-component model, Sham et al.^[55] derived closed-form

expressions of the non-centrality parameter, λ_s , per sib pair. A critical value is obtained based on the required significance level and the central Chi-square distribution. Then the required total non-centrality, λ_T , can be calculated based on the required power, the critical value, and the non-central Chi-square distribution under alternative hypothesis. The number of required sib pairs is given by

$$N = \lambda_T / \lambda_s$$

The non-centrality parameter per sib pair is:

$$\begin{aligned} \lambda_s \approx & V_A^2/8 + 3V_D^2/16 + V_A V_D/4 \\ & + 7V_A^4/64 + 63V_D^4/512 + 45V_A^2 V_D^2/63 \\ & + 7V_A^3 V_D/16 + 31V_A V_D^3 \\ & + V_S[3V_A^3/8 + 15V_D^3/32 + 9V_A^2 V_D/8 + 21V_A V_D^2/8] \\ & + V_S^2[3V_A^2/8 + 9V_D^2/16 + 3V_A V_D/4] \end{aligned}$$

for linkage analysis

$$\lambda_s = (3V_A/2 + 5V_D/4)/(V_N + 2V_S)$$

for association test based on difference between-sibship means, and

$$\lambda_s = (V_A/2 + 3V_D/4)/V_N$$

for association test based on difference within sibship, where V_A , V_D , V_S , and V_N are the additive, dominant, residual shared, and residual nonshared proportions of variance. If the association test is based on individual differences, then the non-centrality per sib pair is the sum of the non-centrality parameters per sib pair of the between-sibships and within-sibship tests. The critical value is 13.8 for a required significance of LOD = 3. With this critical value, the total non-centrality to have 80% power is 20.8. So given V_A , V_D , V_S , and V_N , one can calculate N , the required number

of sib pairs. Purcell, Cherny, and Sham^[56] developed software for sample size calculation, which is available online (<http://pngu.mgh.harvard.edu/~purcell/gpc/>). The closed-form formula of sample size calculations for a popular association test, the transmission disequilibrium test that is not discussed in this article, can be found in Iles.^[57]

Finally, it is expected that the future of genetic mapping will be influenced by the emerging microarray technologies. Genotypes and gene expressions of thousands of genes can be obtained simultaneously using microarrays. This provides huge amounts of data. Some statistical issues in microarray data analysis are discussed in Smyth, Yang, and Speed.^[58] One of the biggest issues with such data is that of multiple statistical testing. A possible solution is to use linkage analysis to locate the approximate locations of QTL and then use microarray to study genes around those locations. Linkage/LD analysis methods can also be extended to microarray data.^[59]

ACKNOWLEDGMENTS

The Collaborative Study on the Genetics of Alcoholism (COGA) (Principal Investigator: H. Begleiter; Co-Principal Investigators: L. Bierut, H. Edenberg, V. Hesselbrock, B. Porjesz) includes nine different centers where data collection, analysis, and storage take place. The nine sites and Principal Investigators and Co-Investigators are: University of Connecticut (V. Hesselbrock); Indiana University (H. Edenberg, J. Nurnberger Jr., P.M. Conneally, T. Foroud); University of Iowa (S. Kuperman, R. Crowe); SUNY Downstate Medical Center (B. Porjesz, H. Begleiter); Washington University in St. Louis (L. Bierut, A. Goate, J. Rice); University of California at San Diego (M. Schuckit); Howard University (R. Taylor); Rutgers University (J. Tischfield); Southwest Foundation (L. Almasy). Zhaoxia Ren serves as the NIAAA Staff Collaborator. This national collaborative study is supported by the NIH Grant U10AA008401 from the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the National Institute on Drug Abuse (NIDA).

In memory of Theodore Reich, M.D., Co-Principal Investigator of COGA since its inception and one of the founders of modern psychiatric genetics, we acknowledge his immeasurable and fundamental scientific contributions to COGA and the field.

Global Database and System

Alice T. M. Hsuan

Aventis Pharmaceuticals, Inc., Bridgewater, New Jersey, U.S.A.

Patrick Genyn

Johnson & Johnson PRD, Raritan, New Jersey, U.S.A.

Abstract

This entry briefly touches upon the system architecture and the methodology applied to support the development, deployment, and maintenance of such a validated system. It also devotes time to the data components of such a standardized database that are based upon a simple implementation of data-warehouse techniques.

INTRODUCTION

Standardization is a generic solution applied in business reengineering. Analysis of the clinical data management, statistical analysis, and reporting processes has identified several elements where standardization would result in time savings. Analysis has identified the database as the true center of the clinical development process. In the database, the “upstream” of clinical research raw data obtained in clinical trials, transformed in analyzable variables, meets the “downstream”—statistical analysis and reporting and clinical reporting. Standardization of this element will yield large time-saving benefits for the development process and higher-quality databases and reports; in addition, it will make more effective use of available resources. At the same time, a standardized database will allow for different modes of data entry, e.g., centralized as well as geographically distributed. It will also take advantage of technological changes such as electronic data capture versus manual data entry methods and provide customized analyses to meet different regulatory preferences in different countries and to efficiently answer additional regulatory requests during the review process. Standardized databases also provide the opportunity to harmonize and streamline the systems for clinical data management and statistical analysis. Applying such standardized systems will definitely result in consistent and comprehensive results and high-quality reporting, independent of where the system is applied in a decentralized approach of processing clinical trials.

This entry will give an overview of the requirements leading to such a standardized environment. It will briefly touch upon the system architecture and the methodology applied to support the development, deployment, and maintenance of such a validated system. A section is devoted to the data components of such a standardized database that

are based upon a simple implementation of data-warehouse techniques. The last sections will briefly lay out the transition into a standardized approach to processing clinical data and the critical success factors involved.

REQUIREMENTS ANALYSIS

With the guidelines of the International Conference on Harmonization (ICH) of Technical Requirements for Registration of Pharmaceuticals for Human Use^[1] in place, regulatory submissions to different authorities, such as the Department of Health and Human Services, the Food and Drug Administration (FDA), and the European Agency for the Evaluation of Medicinal Products (EMA), can be based on studies conducted all over the world. Consequently, studies conducted in the United States are used for submissions to EMA, and studies conducted in the rest of the world can be used in a new drug application (NDA) submitted to the FDA.

Managing, analyzing, and reporting individual trials can be done independently. However, consolidating the data and the results, for instance, into integrated summaries for safety and efficacy, can become a very challenging task when the databases of the individual trials were designed and constructed without having this final global objective of integration in mind. Therefore it is necessary to define and construct similar databases for each trial in terms of structure and content that are based on similar protocols and case report forms (CRFs).

In a decentralized environment for processing clinical data, the likelihood of duplicating work is always present. Standardized databases and systems, however, provide the opportunity to leverage resources globally by reusing database designs and programs from one trial to another. Appropriate and to-the-point communication is

an important and necessary proactive tool in leveraging efforts around the globe.

Standardized approaches in clinical databases and systems, leveraging resources by reusing designs and programs, and standardizing the processes of data management and statistical analysis are solutions for shortening the time to the market and for producing higher-quality databases and reports. However, these solutions do not guarantee these important results when the approach is not global and applied in all departments involved in clinical trials. Proactive management and careful planning are key factors in achieving those quality and time objectives.

Many regulatory authorities, such as the FDA and the EMEA, and other organizations, such as ICH and the International Organization on Standardization (ISO), are also imposing more strict regulations in the area of computerized systems.^[2] These regulations require that a pharmaceutical company be able to show at any time that the applied computer systems produce reliable, accurate, and complete data and results. All requirements mentioned in this paragraph will help in validating the programs and systems used for clinical data processing; however, the challenge of building and, especially, of maintaining a validated system is still there and must be a goal for all levels and functions in the different departments involved.

SYSTEM ARCHITECTURE

The architecture of a clinical system needs to be considered from the perspectives of data management, statistics, and system development. The foundation of the architecture is the physical computing environment. It is essential to separate the computing environment into three distinct environments—development, testing, and production—so that each function can be performed without adversely affecting other functions.

The development environment needs to be a very open one in which the developers have few restrictions. The developers should be able to try out as many alternatives as possible for designs and programs, some of which may even affect other developers in a negative way, such as bad performance or disk congestion. Ultimately, one developer could even cause the computer system to crash. However, by applying a split environment, such a tryout should not affect the production environment or the user acceptance environment because this environment will be separate.

User acceptance is a formal stage during development and testing of a computer system, and the results of the acceptance test are part of the validation package. Therefore the environment for this function needs to be more controlled and restricted as compared to the development environment and should be set up according to formal installation guidelines. At the same time, a user, being very familiar with real data, expects copies of real data or simulated data in the test environment. The user

can then use and manipulate these data to cover as many test scenarios as possible.

The actual processing of the clinical trial data is performed in a secured, validated production environment that is separated from the development and testing functions. The entire physical computing environment as part of the system architecture is depicted in Fig. 1.

The next building block in this computer environment is the data. The database containing the data refers in a broad sense to a “knowledge database” of a clinical project for developing a compound of a certain indication and formulation. The limits are:

Upstream: the construction of a normalized, relational, “raw” database, the design for which is based on the layout of the case record forms. This database contains the actual data collected using the CRF, diaries, quality-of-life questionnaires, etc.

Downstream: datasets containing the data for the tables and figures that format the output of the statistical analysis, and which are used for the clinical trial report and its addenda.

Another level in the hierarchy of the system architecture consists of the basic software for storing, retrieving, and analyzing data. A relational database management system (RDBMS), such as Oracle®, is most often used for storing data in a normalized and structured way. Clinical data management systems installed upon such as RDBMS are used for entering, cleaning, and reviewing the data. Examples are Clintrial™, Recorder™, and Oracle Clinical™. Statistical analysis of the clinical data is supported mostly by a separate package, such as SAS® or SPlus™. However, this package is closely integrated with the RDBMS containing the raw data.

A modular approach to developing systems will result in a very maintainable system. Therefore the system can be split into a number of tools and a number of subsystems. These tools and subsystems form the last level of the infrastructure hierarchy.

Fig. 1 The system architecture supports system- and trial-specific development in a validated environment

A subsystem will have a very specific function supporting a specific task in the process. An example of such a system is the data display subsystem that provides computer-based CRF printouts. These are used for evaluating the trial database; in addition, they are included in submissions to regulatory agencies. Another example of a subsystem is the efficacy system that analyzes all types of efficacy data: discrete, ordinal, and continuous.

Tools, on the other hand, do not support a specific task as a subsystem does, but is a piece of code with specific input and output that can be used for building the subsystems. In other words, the tools are the building blocks for subsystems. Tools can have different objectives, such as data handling, graphic representation, reporting, and applied statistics. Examples are tools to merge two or more datasets, to create summary reports, to output to a word processor, and to calculate the *p* value according to a specific statistical test.

DATA COMPONENTS

The global database contains many types of data and is used for many purposes. It will be much easier to manage the complex data by separating them into logical components. One such way is to separate them into the following five components (see Fig. 2).

- 1. The first component contains all data collected in a clinical trial—whether they be paper CRFs, ancillary data on tape, or other paper-based or computer-based data. These assorted data are named A database.
- 2. The second component is the base physical CRF database, the B database. This database is usually a relational database that contains raw CRF data and other ancillary data and that is organized in a normalized structure most suited for data entry.
- 3. The third component, the C database, is intended for clinical usage. The C database structure provides a view into the raw CRF data in the B database, but it

Fig. 2 The different database components enable an efficient workflow by mirroring the processes in data management and biostatistics

is organized in a denormalized structure most suited for retrieval and data review. Dictionaries are linked to the C views.

- 4. The fourth component, the D datasets, is designed for data analysis. The D database is constructed by adding calculated values, derived variables, and analysis decisions to the B database. Statisticians provide the requirements and specifications of the D database. The D datasets are usually in SAS format. They are organized on a subject level and include separate datasets for demographics, adverse events, efficacy, etc.
- 5. The fifth component contains the electronic outputs of the statistical summary and analysis, the E datasets. The statistical subsystem generates statistical summary and analysis outputs, i.e., summary tables, listings, and graphics.

SYSTEM DEVELOPMENT

Methodology

One of the most commonly applied development and qualification methodologies is the V model.^[3] This model is very simple and straightforward and is schematically described in Fig. 3.

- 1. The first step is to specify the system concept, including the scope of the project, a preliminary project schedule, and a first assessment of costs and resources needed.
- 2. The next step is to define and formalize the user and functional requirements of the system.^[4] The system requirement specification (SRS) describes each of the essential requirements of the software and the external interfaces. One or more reviews will be performed to verify its compliance with stated user requirements.
- 3. After approval of the SRS, the design specifications are formalized in the system design description (SDD) for the system architecture, software components, interfaces, and data. One or more reviews will be performed to ensure that the SDD for a given module achieves the objectives provided in the applicable SRS.
- 4. The system is then built during step 4, according to programming guidelines and naming conventions. Every developer performs construction testing that is freeform testing; however, some documentation is maintained. The objective is to ensure that the programming was carried out properly and that individual modules meet their specifications.
- 5. During step 5, technical testers will perform verification, in which formal testing is performed, independent of the developer, in a separate test environment.

Fig. 3 The V model is an accepted development methodology with built-in validation components

The objective is to ensure that the programming of modules and interfaces was done properly and that the resulting product conforms to design specifications.

6. System qualification (“user acceptance testing”) during step 6 is a formal testing performed in an operating environment that is equivalent to the one used for normal operations. The objective is to ensure that the integrated system performs as expected under normal working conditions. System qualification consists of installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ).

Validation

In the computer business, many definitions and approaches for the validation of computer systems are available. The definition applied for the qualification of the system is the following:

Validation of a system is to establish documented evidence that provides a high degree of assurance that a specific process will consistently produce results meeting its predetermined specifications and quality attributes.

The implementation of this validation approach resulted in three formal stages of validation: installation qualification, operational qualification, and performance qualification. Every qualification phase consists of three steps: defining the plan for qualifying the system, defining and executing the test scripts, and writing a summary report of the qualification. These steps are formally approved and

signed off by the system owners. This process is repeated for every qualification.

The IQ will demonstrate that the computerized system installed is the system designed to meet the requirements. The IQ will contain the evidence that the computerized system has been installed in an appropriate environment and that all system documentation is in place to start the use and maintenance of the system.

The OQ will produce the evidence that the system meets all its requirements by means of functional testing of the system under test conditions. The OQ will demonstrate that the system performs as specified according to predefined test scripts that are executed in a separate test environment but within the boundaries of normal usage of the system.

The PQ provides evidence that the system functions as intended by the user, using the defined procedures. The PQ will guarantee that the necessary standard operating procedures are in place, that users are properly trained, that errors are tracked and managed, and that changes to the system are controlled, etc.

MAINTENANCE

Change Management and Training

Systems to support clinical data management and biostatistics are very complex and not straightforward to use. Change management of people and customized training sessions are key solutions to a successful implementation and delivery of such a system.

A formal definition of change management is:

The process of aligning an organization's people and culture with changes in strategy, structure, and systems.

A formal change management approach will clearly define the customers and all other people that are directly or indirectly involved in the project and how they will be affected by the implementation of the system. By laying-out this structure, it becomes obvious who can help in implementing the system and who might be obstructive. The change management approach must be supported by a good communication plan. Having all these parts of a change management procedure defined, the actual change management can start during the development of the system, way before the actual implementation.

Adequate training sessions are part of the implementation of a good change management procedure and of performance qualification. The audience for the training for this system is very heterogeneous, e.g., technical and nontechnical people, or people from different functional areas, such as data management, biostatistics, and medical writing. Also, before a new hire can start working with the system, a more personalized training is required.

The training therefore is divided into three parts. The first part is an introduction to the new system. The second part explains and clearly defines the rationale behind the data management databases and systems and the biostatistics databases and systems. Newly introduced definitions, structures, techniques, and tests, among other items, are explained in detail, along with why a certain solution is chosen. The third part of the training package consists of technical usage of the system and is focused primarily on technical people such as database administrators, analysts, and programmers.

Change Control

Research in general and clinical research in particular are very dynamic and change very frequently. Clinical trials within the same development plan will vary; clinical trials can have a standard part, e.g., safety, and will have a very specific part as well, e.g., efficacy. Many changes and enhancements will be requested of a system supporting the process of analyzing clinical data. A change request is a request to modify one or more existing deliverables, such as documents or system components, for reasons other than nonconformance, and which have a direct impact on the configuration of the system.

A good clinical practices (GCP) system must remain in a validated state during its operational use. All changes to the system have to be recorded and evaluated for their impact on the validation status. If necessary, the system owner will perform a repeat of validation activities or have them performed. Therefore it is crucial to have a good change control approach in place to track, resolve, and

implement changes to the system. The main objectives of the change control procedure that is applied is to collect all bugs, anomalies, and enhancements, to track these requests from originator to implementation of the change, and to document changes in code, documentation, procedures, etc. The impact of such a system change on cleaned and closed databases or on reported trials needs to be carefully assessed because clinical development programs generally span many years.

TRANSITION

The introduction of a new clinical database and system is always complicated by the question of how to handle the ongoing trials, existing databases, and legacy systems. It is not possible to leave all current databases and systems to run their own course because clinical programs usually last many years. It is also not possible to move all current databases and systems into the new one, due to incompatibility and high cost. Therefore decisions regarding the transition level for the current database and system need to be made. The transition level may depend on the layout of the CRFs, the programming status, and the submission status. One other factor determining transition level is the balancing of the benefits with the cost in resources and budget. After a detailed inventory, the transition level may range from no conversion to full conversion. For example, we may opt not to convert projects without a plan for further development, and convert only integrated safety-summary-related safety data for projects that are at the submission stage. A detailed transition plan, including time schedule, resource needs, cost, and transition level, will provide a guide as to when, what, and how to transition all existing databases and systems.

CONCLUSION

The successful development and implementation of a new global system require both good system development methodology and good process. In previous sections, the importance of training and transition when implementing a new system was discussed. Throughout the life of the system, all involved parties need to co-own the system by being actively involved in the design, planning, development, implementation, and maintenance of the system. The involved parties include users and customers from all relevant sites of the company. Good project management in planning, resource, and communication are critical in ensuring the success of system development.

The main objective of a global clinical system is to shorten the drug development time while improving the quality of clinical data, analysis, summary, and reports. A good system alone will not reach this goal. It is necessary to review, modify, or even reengineer the analysis process,

from finalized protocol and CRFs to the generation of individual and integrated reports. The analysis process conducive to up-front planning, good communication and teamwork, and global collaboration will make optimal use of the global system. Coupling the new process with the new global clinical database and system will achieve the benefits of improved submission quality, synergy among sites, shared resources among sites, shortened submission preparation time, shortened response time for regulatory agency inquiries, and an enabling of the electronic data review internally and by the regulatory agencies.

Good Clinical Practice (GCP)

Mamoru Narukawa

Division of Pharmaceutical Medicine, Kitasato University Graduate School, Tokyo, Japan

Masahiro Takeuchi

Kitasato University Graduate School, Tokyo, Japan

Abstract

Clinical research is essential for the progress of medical science. This entry reviews the ethical and research guidelines for good clinical practice meant to be understood as international standards.

Keywords: Declaration of Helsinki; Good clinical practice; Harmonization.

INTRODUCTION

Clinical research is essential for the progress of medical science. Because it involves human subjects, their rights, safety, and well being must be protected, and the research should bring about meaningful results. Good Clinical Practice (GCP) is an ethical and scientific quality principle for designing, conducting, and reporting clinical research.

Originating from the Declaration of Helsinki, guidelines and rules named GCP have been developed, adopted, and implemented in several countries/regions, and these GCP guidelines have been in the process of international harmonization. The internationalized GCP guideline is expected to enable and to promote multi-regional clinical trials and a mutual acceptance of clinical trial data worldwide.

Because statistical justification of clinical research is a necessary condition for the fulfillment of scientific and ethical quality, statisticians' good understanding of GCP guidelines and their active participation in the research process are expected.

CLINICAL RESEARCH AND GOOD CLINICAL PRACTICE

Clinical research is an experimentation involving human subjects with a view to judging the effect of medical intervention, learning the natural course of a disease, and/or investigating factors that cause a disease. Although in vitro studies and nonclinical (animal) studies are essential and important experimental processes in medical science, information obtained from such studies is not always sufficient for clinical use. And even when the results of nonclinical studies suggest the medical intervention's efficacy and safety, we must reaffirm its result on human beings before applying it generally in clinical practice.^[1] The Declaration

of Helsinki says, "Medical progress is based on research that ultimately must include studies involving human subjects."^[2] This is the basis for necessitating the conducting of clinical research.

Considering such nature of clinical research, we must take care that the rights, safety, and well being of subjects who participate in the research are protected throughout the process. Good Clinical Practice is an ethical and scientific quality principle that is applied in designing, conducting, and reporting medical research that involves the participation of human subjects.^[3]

ETHICAL AND SCIENTIFIC QUALITY OF CLINICAL RESEARCH

Declaration of Helsinki

The Declaration of Helsinki, which was adopted by the 18th World Medical Association (WMA) General Assembly in Helsinki in June 1964, has been acknowledged as the cornerstone of research ethics to provide guidance to physicians and other participants in medical research that involves human subjects.^[2] It is a code that was declared based on the following, seemingly opposing, two principles:

- a. Physicians should give priority to protecting their patient's health over everything else.
- b. Experimentation involving human subjects is essential for the progress of science as well as for the relief of human beings who are suffering from diseases.

The declaration aims primarily at protecting the personal integrity and the welfare of subjects who participate in clinical research. Basic principles described in the declaration are shown in [Table 1](#).

Table 1 Basic Principles of the Declaration of Helsinki

- The well-being of the individual research subject must take precedence over all other interests.
- Medical research must conform to generally accepted scientific principles.
- A protocol, which describes the design and the performance of the research study, must be submitted for consideration, comment, guidance, and approval to a research ethics committee before the study begins.
- Every medical research study must be preceded by careful assessment of predictable risks and burdens in comparison with foreseeable benefits.
- Potential subjects must be adequately informed of the aims, methods, any possible conflicts of interest, the anticipated benefits and potential risks of the study, and others, and the subject's freely given informed consent must be obtained.

Among them, articles related to the subjects' informed consent and the peer review of protocols by the Institutional Review Board (IRB) are two key practical elements. The declaration has been amended several times so far, and the article related to the IRB (called "Research Ethics Committee" in the declaration), which was not included in the declaration when it was initially adopted in 1964, was added at a Tokyo amendment in 1975.

Now many countries and medical associations endorse the Declaration of Helsinki as their ethical code for clinical research.

Quality Assurance and Quality Control

The aim of quality assurance and quality control is to ensure the reliability of the data obtained in clinical research as well as to ensure the protection of human subjects from research risk. In other words, it is to guarantee that clinical research is conducted according to GCP guidelines.

In such activities, standard operating procedures (SOPs) and quality assurance units (QAUs) play key roles to achieve its aim. The SOPs are written instructions describing the general operations to be performed in proceeding with clinical research. Sponsors, investigators, and other medical professionals who are involved in clinical research should be fully acquainted with these instructions, and should fulfill their responsibilities. The QAU is responsible for surveying the operations related to clinical research in accordance with SOPs, and ensuring that the generated data will satisfy the requirements for quality.

Throughout the research, monitoring and audit are particularly important to assure quality. As for clinical trials sponsored by pharmaceutical companies, monitoring and audit by sponsors throughout the trials are essential, while the regulatory authorities also audit the trial independently. The monitoring and audit serve not only to assure data reliability but also to familiarize investigators and other medical professionals with the regulations and rules of clinical

trials. This will also lead to the improvement of the quality of clinical trials.

Thus the implementation of GCP guidelines will be reinforced and ensured by the monitoring and audit by the regulatory authorities as well as by the sponsors.

HISTORY OF GOOD CLINICAL PRACTICE IMPLEMENTATION BY THE UNITED STATES, EUROPEAN UNION, JAPAN, AND WORLD HEALTH ORGANIZATION

United States

The requirements for GCP were established as a matter of urgency by the United States in the early 1970s, responding to gross misconduct and, in many instances, fraud in clinical trials.^[4] A variety of proposed rules and regulations have been published between the latter half of the 1970s and the first half of the 1980s under the pretext of protection of human subjects and rules of new drug application (NDA).

It is well known that there exist no comprehensive regulations named GCP in the United States. The U.S. GCP comprises several federal regulations and other guidelines. The main components of the U.S. GCP are shown in Table 2.

The Code of Federal Regulations, Parts 50 and 56, describe the issues concerning ethics such as the rules and procedures for informed consent, and the role and responsibilities of IRBs, respectively. In Part 312, the responsibilities of the investigator and the sponsor/contract research organization (CRO) in conducting clinical trials are prescribed under the rules of investigational new drug application (IND). Part 314 sets forth procedures and requirements for the submission to, and the review by, the U.S. Food and Drug Administration (FDA) of applications to market a new drug.

The Compliance Program Guidance Manual is a manual for on-site inspection of IRBs, sponsors/CROs/monitors,

Table 2 Main Components of the U.S. GCP

Title 21 Code of Federal Regulations
Part 50: Protection of Human Subjects

Institutional Review Board
Sponsors, Contract Research Organizations, and Monitors
Clinical Investigators

and investigators by the FDA staff, and explains the procedures, points for inspection, etc.

Over the years, these are updated and modified to include, for example, the 21 CFR Part 54 financial disclosure by clinical investigators. This is a regulation that requires an applicant to disclose certain financial arrangements between sponsors of the covered clinical trials and the investigators, to avoid the situation in which those arrangements could be a potential source of bias in the trials.

The U.S. FDA started audits of the work of clinical investigators in 1962, and audits on routine basis have been conducted since 1977.^[5] Common deficiencies following FDA site inspections for 2,711 investigators in North America between 1997 and 2008 are shown in Table 3. Common deficiencies include a failure to follow investigational plan as well as inadequate and inaccurate records (Table 3).^[6]

When deficiencies are found as a result of such audits, which indicate that the investigator has repeatedly or deliberately violated relevant regulations or has submitted false information to the sponsor, the FDA will initiate official actions including the measure of so-called “disqualification.” This means that the investigator may not use investigational drugs in the future.

European Union

The concept of GCP in European Union (EU) countries dates back to the 1960s, with the Nordic countries pioneering the concept around the ethical responsibility of the clinical investigator. Since those days, regional and local Independent Ethics Committees (IECs) have been established in EU member countries, applying the principles of research ethics based on the Declaration of Helsinki. The IEC is a committee that assesses the project’s reliability and validity, whether it entails the risks of harm or discomfort for research subjects, and estimates the anticipated value of the knowledge to be gained. The IEC examines whether the risks of harm or discomfort are balanced against the benefit, and whether the information and consent procedures proposed are appropriate in light of the ethical principles.^[7]

Table 3 Common Deficiencies Found in the FDA Audit for Clinical Investigators in North America (2,711 Investigations Between 1997 and 2008)

Most common deficiencies	Percentage
Failure to follow investigational plan	34.0
Inadequate and inaccurate records	23.7
Inadequate drug accountability	9.4
Inadequate informed consent form	9.1
Failure to report adverse drug reactions	8.2

From Ref. [6].

In July 1991, the Enforcement of the EEC Note for Guidance: “Good Clinical Practice for Trials on Medicinal Products in the European Community” was issued. This enforcement was setting into operation the GCP guidelines, but was not yet legally binding at that time. Then, in September 1991, the European Commission (EC) Directive 91/507/EEC, “Analytical, pharmacotoxicological and clinical standards and protocols in respect of the testing of medicinal products,” was published. By this enforcement, EC member countries were obliged to bring into force their laws, regulations, and administrative provisions necessary to comply with the directive, requesting all clinical trials to be designed, implemented, and recorded in accordance with the GCP guideline by January 1992.

In May 2001, the Directive 2001/20/EC of the European Parliament and of the Council on the approximation of the laws, regulations, and administrative provisions of the member states relating to the implementation of GCP in the conduct of clinical trials on medicinal products for human use was published. It finally came into effect in 2004 with the intention of streamlining the process of clinical trials throughout Europe. However, it was reported to have had negative impact on clinical trials, especially investigator-initiated academic research, because of the increased responsibility and bureaucratic burden.^[8] A system of routine GCP inspection has been in place since 2006.

Japan

The history of GCP in Japan is relatively new. The first GCP in Japan was published in 1989, as a notification of the Director General of the Pharmaceutical Affairs Bureau, Ministry of Health and Welfare (MHW). Its main principles were: (i) proper contract between the sponsor and the medical institution; (ii) establishment of IRB in the medical institution; (iii) protection of subjects’ rights; and (iv) record keeping. This old GCP had some peculiar aspects such as: (i) influential professors (called “principal investigators”) had clout with clinical trials and were in charge of crucial parts of the trial, including preparation of protocols and study reports; (ii) sponsors were not able to conduct on-site monitoring and source data verification; and (iii) informed consent obtained orally was accepted.

Then, in April 1997, a new GCP guideline, which was based on the ICH GCP (see “International Harmonization of Good Clinical Practice”), was introduced. By the adoption of this new GCP, Japanese GCP-related regulations had been replaced by international norms.

The MHW/PMDA (Pharmaceuticals and Medical Devices Evaluation Agency) has been conducting audit for clinical trials for regulatory registration on medical institutions including investigators as well as sponsors since 1993. Table 4 summarizes common deficiencies found in the audit for hospitals in fiscal year 2004, responding to 50 NDAs in the period.^[10] While Japanese GCP audits are

Table 4 Common Deficiencies Found in Japan MHW/PMDA Audit for Hospitals (from April 2004–March 2005)

Deficiencies	Number of findings in 114 audits/189 trials
Qualification of hospitals not met	1
Lack of appropriate SOPs for hospitals and IRBs	18
IRB not appropriately worked	76
Inappropriate contract between sponsors and hospitals	7
Protocol deviation	374
Incorrect/insufficient CRFs	222
Inappropriate informed consent	24
Unsatisfactory investigational drug accountability	8
Inappropriate archives	89

From Ref. [9].

targeted on clinical data and submitted documents, audits by the U.S. FDA are mainly focused on the investigators.

If critical deficiencies in clinical trials are found, official actions would be taken in the form of rejection of the submitted study results.

The implementation of the new GCP guideline has improved the ethical and scientific quality of trials conducted in Japan. It also leads to the harmonization of regulatory practice concerning clinical trials that contributes to the mutual acceptance of foreign clinical data.

World Health Organization

The World Health Organization (WHO) had been developing a GCP guideline named “Guidelines for Good Clinical Practice (GCP) for Trials on Pharmaceutical Products” in consultation with national drug regulatory authorities within WHO’s member states, and it was finally published in 1995.^[11] A number of developing countries have no national regulations for clinical trials or the regulations require supplementation. The establishment of internationally accepted GCP guidelines would be a great value in order to establish globally applicable standards for the conduct of biomedical research on human subjects, considering the future situation where more clinical trials would be conducted worldwide, including developing countries.

INTERNATIONAL HARMONIZATION OF GOOD CLINICAL PRACTICE

The activities for international harmonization of technical requirements for the registration of pharmaceuticals for human use, called ICH, have been carried out in the past decades by the EU, Japan, and the United States. The ICH is an international conference with the aim of harmonizing

technical requirements for NDA in the three regions and of promoting mutual acceptance of NDA data and, as a result, of providing good new medicines to patients sooner. More than 60 harmonized guidelines have been developed in the areas such as quality, safety (nonclinical studies), and efficacy (clinical studies).

In the area of efficacy, the mutual acceptance of clinical trial data (i.e., utilization of clinical data collected in foreign countries for NDA without conducting additional domestic trials) is a key issue. Clinical trial data with ethical and scientific quality are the prerequisite for considering mutual acceptance.

Good Clinical Practice is one of the topics selected as an issue for harmonization in the efficacy area. The objective of the ICH GCP guideline is to provide a unified standard for the EU, Japan, and the United States to facilitate a mutual acceptance of clinical data by the regulatory authorities in these regions.^[13]

Table 5 shows a brief history of the development and implementation of the ICH GCP guideline. The guideline was developed with consideration of the GCPs of the EU, Japan, and the United States, as well as those of Australia, Canada, the Nordic countries, and the WHO.

Members agreed on the draft guideline in May 1995, and the draft was circulated for comments in each region. After discussing comments submitted by relevant parties in the regions, the members reached an agreement on the final document. Regulatory authorities of the EU, Japan, and the United States have adopted and published the final guideline according to their domestic procedure.

The principles of ICH GCP guideline are described in Table 6.

The purposes of the ICH GCP guideline are to protect the rights of human subjects participating in clinical trials and to ensure the scientific validity and credibility of the data collected in the trials. The main principle in the guideline is that the rights, safety, and well being of the trial subjects are the most important considerations and should prevail over the interests of science and society.

Table 5 Brief History of ICH GCP

<i>Development of ICH-GCP</i>	
November 1991	Agreed to start cooperative work toward harmonized GCP
May 1995	Reached an agreement on the draft guideline
May 1996	Reached an agreement on the final guideline
<i>Implementation in each region</i>	
July 1996	EU: CPMP/ICH/135/95/Step 5
March 1997	Japan: PAB Notification No. 430, MHLW Ordinance No. 28
May 1997	United States: Federal Register, Vol. 62, No. 90

Table 6 Principles of the ICH GCP Guideline

1. Clinical trials should be conducted in accordance with the ethical principles that have their origin in the Declaration of Helsinki, and that are consistent with GCP and the applicable regulatory requirement(s).
2. Before a trial is initiated, foreseeable risks and inconveniences should be weighted against the anticipated benefit for the individual trial subject and society. A trial should be initiated and continued only if the anticipated benefits justify the risks.
3. The rights, safety, and well being of the trial subjects are the most important considerations and should prevail over the interests of science and society.
4. The available nonclinical and clinical information on an investigational product should be adequate to support the proposed clinical trial.
5. Clinical trials should be scientifically sound, and described in a clear, detailed protocol.
6. A trial should be conducted in compliance with the protocol that has received prior IRB/IEC approval/favorable opinion.
7. The medical care given to, and medical decisions made on behalf of, subjects should always be the responsibility of a qualified physician or, when appropriate, of a qualified dentist.
8. Each individual involved in conducting a trial should be qualified by education, training, and experience to perform one's respective task(s).
9. Freely given informed consent should be obtained from every subject prior to clinical trial participation.
10. All clinical trial information should be recorded, handled, and stored in a way that allows its accurate reporting, interpretation, and verification.
11. The confidentiality of records that could identify subjects should be protected, respecting the privacy and confidentiality rules in accordance with the applicable regulatory requirement(s).
12. Investigational products should be manufactured, handled, and stored in accordance with applicable good manufacturing practice (GMP). They should be used in accordance with the approved protocol.
13. Systems with procedures that assure the quality of every aspect of the trial should be implemented.

From Ref. [3].

The guideline has an important and beneficial impact on the clinical trials conducted in the three participating regions (Europe, Japan, and the United States) as well as in many other regions throughout the world. And it should fulfill its intended purpose of providing for a more economical use of resources and the elimination of unnecessary delays in the global development and availability of new drugs, and at the same time maintaining safeguards on quality, safety, and efficacy and regulatory obligations to protect public health.^[12]

FUTURE PERSPECTIVES

Biostatistics and Good Clinical Practice

The assurance of quality and credibility of clinical trial data is a prerequisite for the further analysis and evaluation of the trial results. In this context, clinical trials should be conducted to fulfill this requirement according to GCP guidelines. Biostatisticians play one of the key roles in such situations, and they are requested to participate in all stages of the trial process, from designing the protocol, planning the analyses, to preparing clinical study reports in order to assure the scientific quality as well as the ethical quality.^[3]

Because they involve human subjects, clinical trials that result in useless outcome from the viewpoint of their plans and procedures will create ethical problems, and should be avoided by all means. It is the task of biostatisticians to ensure that statistical principles are applied appropriately in clinical trials to demonstrate the drug's safety and efficacy, and make the results meaningful.^[13]

There seem some situations in which biostatistics directly relate to the interpretation and implementation of ethical principles or GCP guidelines in the planning and conduct of clinical trials. One of the examples is the issue related to the use of placebo in controlled clinical trials.

When the Declaration of Helsinki was revised in October 2000, the wording of a paragraph that referred to a placebo control caused a lot of discussion on the circumstances where the use of placebo is allowed.

A strict interpretation of the sentence seemed to rule out the use of placebo in circumstances where proven prophylactic, diagnostic, or therapeutic methods exist. This interpretation brought about concerns such as:

- a. Results of clinical trials, which are placebo-controlled, conducted in developing countries might be used for the benefits of patients in developed countries, as a result of the difference in the availability of a certain proven method between developed and developing countries, which would be a potential control treatment.
- b. Placebo-controlled trials in the areas where proven prophylactic, diagnostic, or therapeutic methods exist are ruled out, although such studies are necessary in some cases in order to obtain sufficient proof of the efficacy of a new treatment.

For this reason, the WMA Council decided to publish a note of clarification on the interpretation of this issue, in that, although the WMA opposes the notion that the nonavailability of drugs should be used as a justification

Table 7 Paragraph 32, the Declaration of Helsinki

The benefits, risks, burdens, and effectiveness of a new intervention must be tested against those of the best current proven intervention, except in the following circumstances:

- The use of placebo, or no treatment, is acceptable in studies where no current proven intervention exists; or
- Where for compelling and scientifically sound methodological reasons the use of placebo is necessary to determine the efficacy or safety of an intervention and the patients who receive placebo or no treatment will not be subject to any risk of serious or irreversible harm. Extreme care must be taken to avoid abuse of this option.

From Ref. [2].

to conduct placebo-controlled trials, a placebo-controlled trial may be ethically acceptable under certain situations, even if proven therapy is available.^[14] A trial of add-on treatment to a standard therapy, or a trial for a minor condition where there is no additional risk or irreversible harm for the subjects in placebo group, may be considered in such a case. Anyway, all other provisions of the declaration, including the subjects' informed consent and the protocol review by IRB, must be observed. The note was finally incorporated into the text, Paragraph 32, in 2008, as shown in [Table 7](#).

The ICH Guideline of Topic E10, Choice of Control Group and Related Issues in Clinical Trials, describes general principles concerning the choice of a control group for clinical trials intended to demonstrate the efficacy of a drug.^[15] Because it would not be feasible to establish an absolute standard concerning this issue, statisticians, together with medical professionals and other experts, should fully participate in the process of protocol development, and discuss the best choice of a control group deeply based on each condition in light of the Declaration of Helsinki, GCP guidelines, and relevant ICH guidelines, so that clinical trials are conducted in a scientific and ethical manner.

Globalization of Clinical Development

If pharmaceutical companies can make an NDA for approval by utilizing clinical data collected in foreign countries without conducting additional domestic trials, it gives a great impact on new drug development from the viewpoint of saving resources as well as providing new drugs to patients in a timely fashion. The ICH Guideline of Topic E5, Ethnic Factors in the Acceptability of Foreign Clinical Data, was established in 1998, and now the acceptability of foreign clinical data for domestic NDA is evaluated according to the guideline from the viewpoint of scientific quality as well as ethical quality. Because the guideline clearly states that clinical trials establishing dose-response, efficacy, and safety should be conducted

according to GCP guidelines, the observance of GCP guidelines is a prerequisite for examining the usability of the result as NDA data in foreign countries.^[16] In this sense, the harmonized ICH GCP guideline plays an important role in the new drug development, which is being internationalized continuously, because the observance of the ICH GCP guideline means the observance of international standard.

These guidelines and others at ICH opened the door for globalization process of clinical development of new drugs. By adopting the principles of the ICH GCP guideline, pharmaceutical companies accelerate their activity of conducting clinical trials worldwide, rather than only in conventional regions such as North America and Western Europe, from the viewpoints of cost, time, and regulatory environment. Over the past years, the share of Phase II/III trial sites for East Europe, Asia, and Latin America has been rapidly increasing. In this situation, there is growing concern among regulators and in public debate about how well these trials are conducted from an ethical and scientific standpoint. In order to address this concern, we need to further promote and establish good clinical practice standards worldwide as well as to strengthen the regulatory review and inspection process and to increase its transparency to assure the rights, safety, and well-being of trial subjects and the credibility of trial data.

CONCLUSION

In the past decades, GCP guidelines have been developed, adopted, and implemented in several countries/regions, and these GCP guidelines have been in the process of international harmonization. It is a natural course as well as a necessary course of action considering the recent internationalization of new drug development, which would enable and promote a mutual acceptance of clinical trial data worldwide. The role of internationalized GCP guideline will become more significant with the advances of medical science.

The adoption of GCP guidelines itself, however, is not a goal, nor does it necessarily assure a good quality of clinical trials. The quality assurance and quality control activities, including monitoring and audit by regulatory authorities as well as sponsors, are expected to ensure and to enhance the level of ethical and scientific quality of clinical research. Also it calls for the active participation of various experts in clinical research including statisticians. The statistical justification of clinical research is a necessary condition for the fulfillment of scientific and ethical quality, and therefore statisticians should be familiarized with GCP guidelines and take part in every stage of the process of clinical research.

Good Laboratory Practice (GLP)

Ying Geng, Baoming Ning, and Dejiang Tan

National Institutes for Food and Drug Control, Beijing, China

Abstract

Good laboratory practice (GLP) is a quality system in which nonclinical health and environmental safety studies are planned, performed, monitored, recorded, archived, and reported. The purpose of GLP is to ensure the adequate environment and the satisfied quality, integrity, traceability, and reliability of safety data through the implementation of well-established quality management system for safety assessment for human and environment. GLP was first introduced officially in 1972 New Zealand Testing Laboratory Act; however, the formal regulatory concept of GLP was created by U.S. Food and Drug Administration in 1978. Other two representative GLP regulations are GLP issued by the U.S. Environmental Protection Agency and GLP harmonized by the Organization for Economic Co-operation and Development. These three GLP regulations are different in scope as well as the definition of nonclinical laboratory study. GLP system shares common principles with laboratory accreditation quality system in a large sense, which differs significantly from accreditation system with respect to the quality assurance system and regulatory purpose. In order to promote the market approval procedure for new products, more and more national regulatory authorities have signed the Memorandum of Understanding or Mutual Recognition Agreement on GLP. Good statistic practice plays the key role in many aspects such as scientific and reliable study design, sampling plan, data analysis, instrument calibration, and decision rules.

Keywords: Good laboratory practice; Laboratory accreditation; Mutual recognition; Organization for Economic Co-operation and Development; Quality system; U.S. Environmental Protection Agency; U.S. Food and Drug Administration.

INTRODUCTION

Good laboratory practice (GLP) is a quality system in which nonclinical health and environmental safety studies are planned, performed, monitored, recorded, archived, and reported. Operated by government, laboratory studies under GLP regulation are conducted to obtain data on properties and/or its safety, intended for submission to appropriate regulatory authorities. After more than 40 years of practice and application in pharmaceutical industry, in a narrow sense, GLP is widely recognized as a common quality standard for organizations that perform the non-clinical safety studies on potential drug or medical devices. However, in a broad sense, the purpose of GLP is to ensure the adequate environment and the satisfied quality, integrity, traceability, and reliability of safety data through the implementation of a well-established quality management system for safety assessment for human and environment.

GLP quality system is different from laboratory accreditation quality systems like ISO17025, WHO/GPCL (Good Practice for Pharmaceutical Quality Control Laboratories). However, the essential principles of the two quality systems have much in common and are comparable to each

other to some extent. With respect to the quality control section of GMP (Good Manufacture Practice), GMP regulations is applied to products for human use, while GLP pertains to quality control system for safety assessment for human and environment. Both GMP and GLP ensure high quality of products and laboratory procedures. With the ever increasing globalization of industries and products, in spite of the fact that there are so many national or regional GLPs, in order to speed up of the market approval procedure for new products, internationally by harmonizing regulation and avoiding the duplicate many time-consuming and expensive test procedures, more and more national regulatory authorities has signed the Memorandum of Understanding (MOU) or Mutual Recognition Agreement (MRA) on GLP.

Since GLP principles ensure that the study falls under a rigorous quality assurance system, neither the scientific validity of method nor the ability to generate accurate and precise measurements, is the main purpose of GLP. In this sense, good statistic practice played the key role in the safety assessment studies in many aspects such as scientific and reliable study design, sampling plan, data analysis, instruments calibration, and decision rules.

NONCLINICAL LABORATORY STUDY AND SCOPE OF GLP

GLP was first introduced officially in 1972 New Zealand Testing Laboratory Act to provide for the development and maintenance of good conformity assessment practice that is consistent with international practice and facilitates trade.^[1] However, the formal regulatory concept of GLP was created by the U.S. Food and Drug Administration (FDA) in 1978.^[2] Other two representative GLP regulations^[3,4] are GLP issued by the U.S. Environmental Protection Agency (EPA) and GLP harmonized by the Organization for Economic Co-operation and Development (OECD). These three GLP regulations are different in scope as well as the definition of nonclinical laboratory study.

GLP scopes described in FDA, EPA and OECD were different to the extent necessary to reflect the agencies' different statutory responsibilities. As reflected by the definition of "nonclinical laboratory study," the FDA regulates studies conducted in the scope of health effects, while the EPA regulates studies conducted in the scope of health effects, chemical characterization, and environmental fate studies. As harmonized by OECD, nonclinical study

referred to an experiment or a set of experiments in which a test item is examined under laboratory conditions or in the environment to obtain data on its properties and/or its safety. Currently, GLP standards have been established across the world, making these standards a universal quality assurance system. [Table 1](#) illustrates the comparison of the definition of nonclinical laboratory study and scope from GLP regulations of FDA, EPA, and OECD.

GLP PRINCIPLES

General GLP principles include (1) organization, personnel, and responsibility; (2) the quality assurance program; (3) facilities; (4) equipment, reagents, and materials; (5) test systems; (6) test and reference items; (7) standard operating procedures; (8) study performance and reporting; and (9) the archives. With the more detailed requirement and development of electronic technology, more principles were implemented such as the principles to the organization and management of multi-site studies,^[5] to in vitro studies,^[6] to computerized systems,^[7] and for peer review of histopathology.^[8]

Table 1 Comparison of the Definition of Nonclinical Laboratory Study and Scope from GLP Regulations of FDA, EPA, and OECD

	FDA	EPA	OECD
Nonclinical laboratory study	Nonclinical laboratory study means in vivo or in vitro experiments in which test articles are studied prospectively in test systems under laboratory conditions to determine their safety.	Study means any experiment at one or more test sites, in which a test substance is studied in a test system under laboratory conditions or in the environment to determine or help predict its effects, metabolism, product performance (efficacy studies only as required by 40 CFR 158.640), environmental and chemical fate, persistence and residue, or other characteristics in humans, other living organisms, or media.	Nonclinical health and environmental safety study, henceforth referred to simply as "study," means an experiment or a set of experiments in which a test item is examined under laboratory conditions or in the environment to obtain data on its properties and/or its safety, intended for submission to appropriate regulatory authorities.
Scope	... for conducting nonclinical laboratory studies that support or are intended to support applications for research or marketing permits for products regulated by the Food and Drug Administration, including food and color additives, animal food additives, human and animal drugs, medical devices for human use, biological products, and electronic products.	(1) ... for conducting studies relating to health effects, environmental effects, and chemical fate testing. This part is intended to ensure the quality and integrity of data ... (2) ... applies to any study described by paragraph "a." of this section which ... (3) It is EPA's policy that all data developed under section 5 of TSCA be in accordance with provisions of this part.	... should be applied to the non-clinical safety testing of test items contained in pharmaceutical products, pesticide products, cosmetic products, veterinary drugs as well as food additives, feed additives, and industrial chemicals. ... include work conducted in the laboratory, in greenhouses, and in the field. ... apply to all nonclinical health and environmental safety studies required by regulations for the purpose of registering or licensing pharmaceuticals, pesticides, food and feed additives, cosmetic products, veterinary drug products and similar products, and for the regulation of industrial chemicals.

HISTORY OF GOOD CLINICAL PRACTICE REGULATION BY THE UNITED STATES, THE EUROPEAN UNION, JAPAN, CHINA, AND THE WORLD HEALTH ORGANIZATION

US Food and Drug Administration

The Federal Food, Drug, and Cosmetic Act, passed by Congress in 1938, gave authority to the FDA to oversee the safety of food, drugs, and cosmetics. The Public Health Service Act requires that a sponsor establish the safety and efficacy of biological products. These laws place on the FDA the responsibility for reviewing the sponsor's test results and determining whether the results establish the safety and efficacy of the product. If the agency accepts that safety and efficacy are adequately established, the sponsor is permitted to market the product.

At the end of the 1960s and the beginning of the 1970s, with a rapidly increasing use of chemical substances and the emergence of "contract research organizations" (CROs), tightened regulatory requirements especially for safety testing of pharmaceuticals became imperative. The "thalidomide disaster" and other safety cases are notable for their severe influence. Under the discrepancies between the data and conclusions submitted to the FDA, a series of hearings on the "Preclinical and Clinical Testing by the Pharmaceutical Industry" were started by US senate. Proposed regulations for GLP in nonclinical laboratory studies were then published by FDA on November 1976. After that, the FDA finalized GLP regulations and published them in the Federal Register on December 22, 1978 (21 CFR 58), and these GLP regulations came into effect on June 20, 1979.^[9]

The FDA performs two types of GLP inspections: routine inspections and "for-cause" inspections. The former are periodic evaluation of a laboratory's compliance with the GLP regulations on an at least once every 2 years basis, and the latter are invoked for one or more serious reasons as follows: deficiencies found in a routine inspection, concerns raised in the study reports submitted, validation of studies submitted, a third-party validation, verification, and investigation of questionable circumstances.^[10]

When failure of the facility to comply with one or more of the GLP regulations or other regulations published in Chapter 21 CFR, adverse effects on the validity of studies, or failure to achieve compliance with regard to lesser regulatory actions was inspected, the FDA would enforce the strategy of disqualification of a testing facility, in which case the facility fails to comply with the GLP regulations.

US Environmental Protection Agency

Confronting with the similar problems as FDA concerns, the EPA published its own GLP standards under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), which regulates pesticides and their safety, and

the Toxic Substances Control Act (TSCA), concerned with chemical substances. The EPA's FIFRA and TSCA GLP regulations were finalized on November 29, 1983, with the FIFRA GLP regulations codified as 40 CFR 160^[11] and the TSCA GLP regulations as 40 CFR 792.^[12] The Laboratory Data Integrity Branch is in charge of the direction of GLP programs, with the primary mission to assure the quality and integrity of studies submitted to the EPA and to assure compliance with the GLP regulations by conduction laboratory inspection and data audits.

The European Union

The first council directive issued in Europe is the 79/831/EEC of 18 September 1979 amending for the sixth time Directive, which regulated that the tests carried out shall comply with the principles of good current laboratory practice. Then in 1987 and 1988, a series of directives were published, the 87/18/EEC, 87/19/EEC, 87/20/EEC, and 88/320/EEC, which regulated that the safety evaluation of chemical substances, medicinal products, and veterinary products in compliance with GLP principle and under inspection and verification of GLP. After that, the two Directives 2004/9/EC and 2004/10/EC were issued, replacing Directives 87/18/EEC and 88/320/EEC, by the European Parliament and the Council of the European Union. These directives (as shown in Table 2) had adopted the principles and the revised OECD Guides for Compliance Monitoring Procedures for GLP.

The OECD took the task of the international harmonization of GLP standards, aiming to avoid nontariff barriers to trade in chemicals, promote mutual acceptance of data, and eliminate unnecessary duplication of labor. As stated by OECD, "to avoid different schemes of implementation that could impede international trade in chemicals, OECD member countries have pursued international harmonization of test methods and good laboratory practice."^[4] In 1979 and 1980, an international group of experts established under the Special Program on the Control of Chemicals developed the OECD Principles of Good Laboratory Practice, utilizing common managerial and scientific practices, and experiences from various national and international sources.

These principles of GLP were adopted by the OECD Council in 1981, as an Annex to the Council Decision on the Mutual Acceptance of Data in the Assessment of Chemicals [C(81)30(Final)].^[13] The OECD GLP regulations were revised and finally adopted on November 26, 1997 [C(97)186/Final].^[4] They were widely introduced into OECD countries. Moreover, many countries have developed GLP standard of their own based on OECD principles. The definition of GLP was first explicated to "nonclinical and environmental safety studies," and the scope was eliminated as "all non-clinical health and environmental safety studies required by regulations for the purpose of registering or licensing pharmaceuticals,

Table 2 Directives Adopted the Principles and the Revised OECD Guides for Compliance Monitoring Procedures for GLP

Council Directive	Contents
79/831/EEC	Council Directive 79/831/EEC of 18 September 1979 amending for the sixth time Directive 67/548/EEC on the approximation of the laws, regulations, and administrative provisions relating to the classification, packaging, and labeling of dangerous substances
87/18/EEC	Council Directive 87/18/EEC of 18 December 1986 on the harmonization of laws, regulations, and administrative provisions relating to the application of the principles of GLP and the verification of their applications for tests on chemical substances
87/19/EEC	Council Directive 87/19/EEC of 22 December 1986 amending Directive 75/318/EEC on the approximation of the laws of the Member States relating to analytical, pharmacotoxicological, and clinical standards and protocols in respect of the testing of proprietary medicinal products
87/20/EEC	Council Directive 87/20/EEC of 22 December 1986 amending Directive 81/852/EEC on the approximation of the laws of the Member States relating to analytical, pharmacotoxicological, and clinical standards and protocols in respect of the testing of veterinary medicinal products
88/320/EEC	Council Directive 88/320/EEC of 9 June 1988 on the inspection and verification of GLP
2004/9/EC	Directive 2004/9/EC of the European Parliament and of the Council of 11 February 2004 on the inspection and verification of GLP
2004/10/EC	Directive 2004/10/EC of the European Parliament and of the Council of 11 February 2004 on the harmonization of laws, regulations, and administrative provisions relating to the application of the principles of GLP and the verification of their applications for tests on chemical substances

pesticides, food and feed additives, cosmetic products, veterinary drug products and similar products, and for the regulation of industrial chemicals.”^[4]

Japan

The GLP regulations were issued by multiple agencies: Ministry of Health, Labour and Welfare,^[14,15] relating to pharmaceuticals, medical devices, and workplace chemicals; Ministry of Economy, Trade and Industry and Ministry of Environment, both relating to industrial chemicals; and Ministry of Agriculture, Forestry and Fisheries relating to pesticides, veterinary drugs, and feed additives,^[16] which were mainly based on Revised Guidance for the Exchange of Information concerning National Programs for Monitoring of Compliance with the Principles of Good Laboratory Practices.

China

The first GLP tentative regulation, “Guidelines of Drug Non-clinical Study Good Laboratory Practice (draft),” was promulgated by the State Science and Technological Commission (the former Ministry of Science and Technology of the People’s Republic of China). In 1993, the national drug administration system reformation occurred, which resulted in the alternation of law enforcement subject. The newly revised tentative guideline of GLP^[17] was then published by China Food and Drug Administration in 1999; final regulations such as “Guideline of Drug Non-clinical Study Good Laboratory Practice”^[18] were published in 2003, to ensure the validity and reliability of nonclinical laboratory studies in order to support the safety of CFDA regulation. The updated regulations were revised in 2017

recently.^[19] Other GLP regulations were issued by the Ministry of Agriculture of People’s Republic of China and the former Ministry of Environmental Protection of People’s Republic of China.

The World Health Organization

The World Health Organization (WHO)/Research and Training in Tropical Diseases (TDR) developed a GLP series in 2001, comprising a GLP Handbook as well as GLP training manuals, with the second edition of GLP Handbook issued in 2009 as well as that of training manuals issued in 2008. WHO/TDR GLP series were developed on the basis of OECD principles, in order to assist countries in conducting nonclinical research and drug development, especially aiming to empower disease endemic countries to develop and lead research activities at internationally recognized standards and quality, and anticipating that the use of GLP resources will help promote cost-effective and efficient preclinical research with a long-term positive effect on the development of products for the improvement of human health.^[20,21]

MUTUAL RECOGNITION

The objective of mutual recognition of GLP signed by two or more countries is to enable the reciprocal recognition of each country’s standard, protocol, test data, and conformity assessments of GLP program for the evaluation of safety, and inspectional procedures are mutually acceptable.

The divergence of technical requirements from country to country was such that industries (such as pharmaceutical industry, food industry, and cosmetic industry)

found it necessary to harmonize the regulation by achieving science-based mutual acceptance of research and development data. FDA has signed MOU or MRA with counterparties of Germany, Sweden, Switzerland, the Netherlands, Italy, Canada, and Japan.

As an international organization with more than 30 member countries, OECD adopted Mutual Acceptance of data (MAD),^[22] which states that data generated in any member country in accordance with OECD GLP principles shall be accepted in other member countries. The MAD system substantially saves governments and chemical producers every year from the expensive and labor-intensive testing.^[23] OECD also implemented nonmember adherents to the MAD system, for the OECD full adherent countries such as Argentina, Brazil, India, Malaysia, South Africa, and Singapore. For the emerging economies such as China, India, and Brazil, international recognized OECD GLP is a suitable template to achieve a global harmonized GLP standard by incorporation with the consideration and concerns of all stake holders.

LABORATORY ACCREDITATION QUALITY SYSTEM AND GLP

The standards of quality system are implemented to quality management of laboratory, aiming at improving the ability to consistently produce valid results. Such accreditation system as ISO/IEC 17025 specifies the general requirements for the competence to carry out tests and/or calibrations. These standards are widely used as a quality system in environmental, food, chemical, and clinical testing laboratories. Testing laboratories seek accreditation by such quality systems to demonstrate their competence.

The most distinctive difference between GLP and laboratory quality system lies in the regulatory control mechanism. GLP compliance is written into law, regulating the studies that nonclinical health and environmental safety studies intended for regulatory submission. To comply with GLP regulations is to assure that work is being performed by qualified personnel, under appropriate direction, in adequate facilities, with calibrated and maintained equipment, using standard operating procedures, documenting raw data, having in-process work inspected, and providing reports that are reviewed by a QA professional.^[9] To this extent, GLP is a quality system aiming at guaranteeing neither scientific validity of method nor the ability to generate accurate and precise measurements.

GOOD STATISTICS PRACTICE AND GLP

GLP principles provide a quality system that ensures the studies are planned, performed, monitored, recorded, archived, and reported under quality assurance. Nevertheless, it is the good statistics practice (GSP) that plays

a key role in many aspects such as scientific and reliable study design, sampling plan, data analysis, instrument calibration, and decision rules. Statistical considerations were important for conducting safety studies, such as sampling plan, conventional statistical power, significance, critical study endpoint, and validation of the study. With the tendency of ever-increasing collaboration with multiple site or laterals, and explosive growing data capacity, statistics was driven to take more and more important part in the design of study plan, the analysis of data, risk assessment, and scientific decision rules.

CONCLUSION

The principles of GLP promote the quality and validity of data generated in the testing of chemicals and prevented fraudulent practices. As a common quality standard for nonclinical safety studies on human and environment safety assessment, GLP has been globally accepted and played an important role over decades of practice. The good statistics practice was implemented in GLP providing a valid and fair assessment of the study conducted.

GLP, ISO 17025, WHO/GPCL and GMP share some essential universal principles: Say what you do and do what you say. With the continuous deepening of economic globalization and fast speed of new technology development, there are increasing demands and challenges in the international harmonization, scientific regulatory technical requirements, and modern technology innovations. In order to promote the market approval procedure for new products, more and more national regulatory authorities have signed the MOU or MRA on GLP. International recognized GLP shall play a key role in global harmonization process by incorporation with the consideration and concerns of all stake holders.

Good Programming Practice (GPP)

Aileen L. Yam

Independent Consultant

Abstract

This entry presents ideas on the fitness, robustness, remodeling friendliness, extendibility, and economy of program construction. The importance of documenting, organizing, validating, and archiving programs, as well as the need to keep updated and to have a cooperative spirit in a shared project, are highlighted.

Keywords: Coding; Designing; Good practice; Programming; Quality; Validation.

INTRODUCTION

The operation of a biostatistics group in the drug development process is analogous to the process of building a house. Data coordinators prepare building blocks and lay a solid foundation. Statisticians are the architects with overall responsibility for the conception and realization of the project. Programmers are the construction engineers who execute the statisticians' plan and transform building materials into a house. In other words, a synergy of efforts among data coordinators, statisticians, and programmers is necessary. Data coordinators ensure the integrity of the data. Statisticians do detailed analysis of the drug, choose appropriate statistical methods, write specifications, and analyze results. Programmers implement statistical rules to convert clinical data into useful information for assessing the safety and efficacy of a drug.

This entry presents ideas on the fitness, robustness, remodeling friendliness, extendibility, and economy of program construction. The importance of documenting, organizing, validating, and archiving programs, as well as the need to keep updated and to have a cooperative spirit in a shared project, are highlighted.

requirements. Quality needs to be defined within business concerns, corporate and industry culture, on the basis of the expected life span of the programming code, and, sometimes, on a project-by-project basis.

In general, quality for programming in the pharmaceutical industry refers to *fitness* (whether the programs meet functional requirements and are suitable for the purpose for which they are intended), *robustness* (accurate and reliable under different programming conditions and data scenarios), *remodeling friendliness* (easy to read, understand, and maintain), *extendibility* (re-usable and automatable to handle multiple studies of the same drug), and *economy* (on time and within budget).

With the stringent requirements, the emphasis here is on programming techniques and processes that build in quality to do things right the first time.

The SAS® System is the most commonly used software in clinical trials so “SASese” is inevitably spoken. However, the general principles discussed within the context of programming in SAS can be applied regardless of the programming tool or language selected. Analogies and simple programming examples are given to make the concepts behind the principles more concrete.

QUALITY IS IN THE EYE OF BEHOLDER?

The goal of good programming practice is quality work. Quality is an elusive term. Quality as practiced may sometimes be different from quality as idealized in theoretical discussions. There are constraints to balance among available resources, budgets, schedules, and programming

DESIGNING

Just as building a house needs blueprints, designing is an important prerequisite for good programming practice before actual coding starts. Winograd et al.^[1] stressed the importance of bringing design to programming. Their book is based on a workshop on software design. Two software developers at the workshop listed the components in the development of designs as understanding, abstracting, structuring, representing, and detailing. The crucial role of design as a counterpart of programming in clinical trials is very similar.

Note: The SAS and all other SAS Institute Inc. product or service names are registered trademarks or trademarks of SAS Institute Inc. in the USA and other countries. ® indicates USA registration.

Understanding involves learning the nature of the drug and the protocol as well as comprehending the analysis specification. What are the rules? Are the rules appropriate, feasible, sufficient, or contradictory? Understanding also means having a good grasp of the data structure, formats, and categories. Are the data standardized across studies? Do the data match the case report form or the protocol requirements?

Abstracting means sketching out the main elements for programming. Are all the requirements covered? Can a consistent vision of all the elements in the whole project be built in, from Investigational New Drug (IND) to New Drug Application (NDA) or Biologic License Application (BLA)?

Structuring entails the ordering of relationships among the elements. Is there logical, functional, sequential, or procedural coherence? Is the layout elegantly clear?

Representing refers to representing the elements in computer language. What are the steps or procedures selected? Are the selections relevant? Will they work in various situations? Do the methodologies conform to the Clinical Data Interchange Standards Consortium (CDISC) standards^[2] and Food and Drug Administration (FDA) requirements?^[3]

Detailing is the careful attention to the fine points of programming. Are the approaches lean, simple, and straightforward? How can programs be written so that they are easy to debug, modify, maintain, and enhance? What are the goals of a specific program? Are the goals to build applications or systems where continuous fine-tuning and addition of features are needed? Or are the goals to write good enough programs for basic operation? What is seen as indispensable in some situations can be unnecessary overhead in other situations.

The process of designing fosters communication among programmers, statisticians, clinicians, and data coordinators, and encourages different perspectives of solutions to problems. Good designs clarify a program and convey the content. Good programmers are designer-programmers. The design approach selected has to be tailored to project needs. Design deals with the issue of whether the programs are *fitting* and appropriate to address the statistical questions of the drug under study.

CODING

In addition to good designs, quality engineering is needed. Good programming practice as defined and illustrated herein is organized around the goals of robustness, remodeling friendliness, extendibility, and economy. Not all of these goals are completely compatible. For example, making a program more robust may add complexity to a program. The pragmatic challenge lies in prioritizing and finding a happy medium among these quality goals.

ROBUSTNESS

Robustness is the most essential characteristic in the construction of a quality program. Robustness encompasses accuracy, reliability, thoroughness, and reproducibility. As a general rule, making a program robust means writing solid code and having a good understanding of how to effectively prevent bugs and how to easily or automatically detect bugs.^[4]

Here is an example of built-in robustness. If you need to create a response flag that indicates an average increase of 1% from baseline over 3 years at each of the scheduled 6-month intervals, you can code the program as follows:

```
if month = 6 and pchange = .50 then response = 1;
else if month = 12 and pchange = 1.0 then response = 1;
else if month = 18 and pchange = 1.5 then response = 1;
else if month = 24 and pchange = 2.0 then response = 1;
else if month = 30 and pchange = 2.5 then response = 1;
else if month = 36 and pchange = 3.0 then response = 1;
else response = 0;
```

If subjects do not follow the study protocol and come in at unscheduled time points or after 3 years, or if there are missing data, the preceding code will not work properly. A more robust way to write the code is:

```
if pchange = month / 12 then response = 1;
else if pchange > 3.0 then response = 0;
```

Not all the programming code can be made robust and elegant simultaneously as effortlessly as this example. It sometimes depends on the level of over-engineering expended to check in every conceivable way and at every conceivable place.

What follows is a discussion of the various aspects of strengthening robustness.

Syntax errors, uninitialized variables, automatic data type conversions, division by zero, unknown formats, undeclared array elements, and merging with repeats of key variables are some of the ordinary types of bugs that usually exist in the early stage of programming development. They are the easiest to locate and fix. Compilers usually give error or warning messages on these kinds of errors.

Logic errors are a less obvious kind of bugs that inhibit the proper function of a program. They are less obvious because the program is syntactically correct but may not give the correct result. An example of logic error is referring to the first or the last observation that has just been deleted. It is very important to test programming code in small chunks. It is also important to know the assumptions behind the design of the program, and to build in

statements to output warning messages if assumptions are violated. Bugs multiply quickly. Any bug found needs to be immediately fixed, especially at a step that supplies data to another step.

A common type of bug is introduced by data. A program may not have accounted for all the data scenarios or for unexpected data errors. For example, the studies of a drug are conducted in both the United States and Europe, and if a programmer expects only inches and centimeters in the conversion of height values, the program will miss the height values that are in meters or have missing units. One way to avoid this kind of bug is to do a frequency check on the unit categories and to write the program based on the frequency results. But the studies may not have been completed when the program is written and new data may create bugs in the program. A more reliable way is to build routines into the program to flag unexpected data values and to output warning messages, or to capture those values and print them out. It also helps to draw a Venn diagram or to sketch out a list to see if all possible combinations of conditions are covered.

Missing values are a type of bug most often neglected by programmers. A simple example is to write a condition for test results of less than 5, to indicate significant improvement; subjects with missing test results end up in the “significant improvement” category:

```
if score < 5 then improve = 'SIG';
elseif score >= 5 then improve = 'NOT SIG';
```

This code is syntactically correct, but there are two other problems besides assigning missing values to the wrong category. First, the length of the variable *improve* is not defined. Its length is defined by the first IF statement. Thus the value of *improve* in the second IF statement is truncated to 3. Second, invalid scores, such as negative scores or zeroes, are not accounted for. One way to prevent the bugs is to change the code to the following:

```
length improve $7;
if score = . then improve = '';
else if 1 <= score < 5 then improve = 'SIG';
else if score >= 5 then improve = 'NOT SIG';
else put 'DATA ERROR: ' SUBJECT = 'subjid'
      'SCORE = ' score;
```

One other kind of data-related bug comes from merging or concatenating data. It is necessary to examine database structures before combining the data, to sort the data and join them by key variables, to keep only the variables in each data set that are necessary in order to prevent variables of the same name from being overwritten in merging, to add debugging code to output warning if the data cannot be combined properly, and to verify the number of observations before and after the data are combined.

In clinical trials, because NDA or BLA submissions usually require the integration of information from several studies of a potential new drug, maintaining internal consistency is a very important aspect of ensuring robustness. Consistency is needed across all studies of the same drug in naming variables, in choosing data type, in formatting and labeling variables, in assigning the values of categorical variables, and in structuring derived data. Here are some reasons why consistency is important:

1. If a character variable is assigned different lengths in different studies, the values of the character variable are truncated when data from the studies are concatenated.
2. If the same variable is given different names in different studies, proper integration of data is not possible until the variable is renamed to the same name in all studies.
3. The effects of inconsistency are subtle; usually there is no error message. It is necessary to adopt a uniform approach for all studies to rule out unexpected errors.

Numeric representation errors, also known as rounding errors, are one type of bug that can crawl into programming code without notice. Fractional values and values that do not have enough storage space have the potential for numeric representation problems. Numeric representation errors propagate. The more computation the values go through, the larger the errors will become. An example of the occurrence of numeric representation errors in programming laboratory data is the comparison of laboratory values to normal ranges, where both the laboratory values and the normal ranges are fractional values. Here are some major ways to minimize numeric representation problems in SAS software:

1. Only use the LENGTH statement or the ATTRIB statement to truncate values when disk space is limited.
2. Use integers if possible.
3. Use the ROUND function or the FUZZ function on fractional values before doing a comparison on the values.

Related to numeric representation errors is mixed variable types that result in automatic data type conversions. Avoid comparing numeric variables with character variables because the comparison figures out the conversion type, converts one type into another, does rounding, and determines the answer.

Hard-coding is a cardinal sin. Hard-coding is usually an attempt to programmatically fix data errors. Hard-coding disrupts the integrity of data and the replication of results. It also undermines the robustness of a program. Data errors are best handled at the source, i.e., in the database.

Using available formats, functions, and routines from software is a way to prevent bugs. The software is usually thoroughly tested before it is released. In SAS software, for example, directly outputting p -values from a procedure into a data set is easier and less error-prone than writing a program to extract the p -values. There is also less chance for error using formats such as PVALUE and PERCENT than building the formats with FORMAT statements. The PVALUE format automatically transforms values of less than zero to the standard SAS output p -value format. The PERCENT format can automatically take care of rounding.

REMODELING FRIENDLINESS

Change is a fact of life in programming for clinical trials. Therefore making a program easy to understand, easy to use, easy to modify, and easy to debug is vital. Some requests for changes are made for cosmetic reasons. Most cosmetic changes are like repainting a house: they are simple and they rarely affect original program design. Requirement or analysis changes are usually structural changes; the sections that are intricately interwoven may need major rework. Changes also arise from error correction.

No matter how big or small changes are, each change requires review of the changed code, testing of the impact of the changes on the whole program, and revalidation and sometimes rewriting of all the results. It is better to funnel all the change requests through lead statisticians or programming managers who are familiar with the intent and the budget of the studies than to make changes on demand. The leads will coordinate the changes where ideas for changes contradict among clinicians, data coordinators, statisticians, medical writers, and the regulatory group. The leads will also separate the wheat from the chaff change requests and will estimate and make sure everyone knows the cost of each change.

To insulate a program from the effects of remodeling, the following are some guidelines to write or revise programs by anticipating and documenting changes:

1. Write simple and straightforward code in a clear layout, and have sufficient comments so that any programmer can understand and modify the code with little chance of introducing bugs.
2. Comply with your company's programming conventions; they are tools to help communicate the nature of a program or a variable. For example, all program names that start with the letter m are macro programs, or all variables that start with an underscore are array variables.
3. Keep the initialization and the reference of variables close together so that they are easy to locate.
4. Do not nest too deep. Cut down interrelated parts to minimize the impact of changes.

5. Global macro variables are convenient to access, but the values of the global macro variables may be inadvertently changed in a program, whereas local macro variables that are confined to a small section of code are easier to maintain.
6. Modularize parts that are likely to change.
7. When there are extensive programming structural changes, it is sometimes easier to rewrite a program than to modify an old one.
8. Avoid tricks; the time spent writing and documenting tricky code is better spent in writing plain code that is easy to maintain.
9. Make changes that are compatible with the existing program design.
10. Adhere to your company's system for documenting and tracking changes.

EXTENDIBILITY

In clinical trials, usually multiple studies are performed on the same drug. A major goal in programming is to attain extendibility. Extendibility here means that the programs are flexible in accommodating varying number of treatments, visits, hours, etc., and are re-usable for many studies. A basic example of extendibility is to make study number a macro variable so that programs can be used for any study with the same data structure and analysis requirements by reassigning the value of the macro variable.

The advantages of extendibility are that reusing the code makes the output identical and that the value of the code increases if the code is re-usable for multiple studies of one or more drugs.

Some of the techniques for building extendible programs are: look for patterns in data and analysis; design easily shared code; make use of macros and parameter-passing mechanism; avoid data-driven coding; modularize parts that are different and make it easy to isolate and replace a section of code; use local macro variables when possible so that it is easy to pull out some parts of the code and plug them into another program.

There is a tradeoff between generality and specificity. The more general and flexible the design is, the harder it is to write the program and to detect bugs, and sometimes the harder it is to use or to modify.

It is usually easier to write general programs for safety analyses than for efficacy analyses because safety analyses tend to be similar, except for the number of treatment groups or visit numbers, while efficacy analyses tend to be substantively different.

ECONOMY

Conventional wisdom in programming defines economy as leanness of programming code. Each and every piece

of code is important and cannot be taken away. In a more practical sense from the viewpoint of research on drugs, economy means completing the project and being able to submit NDAs or BLAs on time and within budget.

Economy is often discussed in terms of computer efficiency and human efficiency. Computer efficiency means minimal use of system resources, such as execution time, input-output time, memory, and data storage. Human efficiency means less programming time spent in designing, coding, validating, documenting, and maintaining.

Some techniques for ensuring computer efficiency are: order IF conditions by decreasing frequency of occurrence; eliminate unnecessary input and output operations; minimize macro reference; compile frequently used macros; use random access (WHERE condition) instead of sequential access (IF condition); use the fewest array dimensions possible; and automate repetitive tasks.

Here is an example of human efficiency in creating a variable called *block* where subjects 1–10 are in block 1, subjects 11–20 are in block 2, and subjects 21–30 are in block 3:

$$\text{block} = 1 * (1 \leq \text{subject} \leq 10) + 2 * (11 \leq \text{subject} \leq 20) + 3 * (21 \leq \text{subject} \leq 30);$$

There is only one statement to type. The tradeoffs are that it is hard to maintain and may lack robustness. The code is fine in this case, because randomization schemes for assigning subjects to blocks are usually established at the beginning of a study and seldom change.

In clinical trials, good programming design, careful algorithm selection, the prevention of errors, and the writing of clean code that is easy to maintain contribute to economy. Having a few dedicated programmers on a project, and not rotating programmers in and out of projects, saves time and increases quality because each additional person added to a project has a learning curve. In addition, economy means joint efforts among data coordinators, statisticians, programmers, and medical writers to increase productivity. Clean and complete data and less rework from rule changes are important. Locate data problems and promptly inform data coordinators to rule out programming errors. Work with statisticians in early stages to reduce the amount of time spent in requirement changes or debugging. If each and every person makes an effort to do the job right the first time, economy is built into the process. It also spares the medical writers from having to rewrite results because of changes or errors.

Economy is integral to the overall program quality but it is not the most critical condition. Priorities need to be established if economy conflicts with other goals, especially robustness.

DOCUMENTATION AND ORGANIZATION

Documentation and organization are controversial topics because they are products of programming style. Rigid

standards cannot be imposed without contention; the best way is to work out a team style. Style is not just a matter of aesthetics; good style communicates content. The essence of good style is discussed here.

Documentation in programming is generally known as comments. Effective comments are not the comments that simply repeat the code; they should explain the objectives at a higher level of abstraction than the code.^[5] Code-level comments can be replaced by good programming style, which includes meaningful variable names, descriptive labels, easily understood logic, well-thought-out design, clear layout, and naming conventions that distinguish among constants, temporary variables, local or global macro variables, loop index variables, and array variables. Good style documents code without extensive comments. The best documentation is self-documenting code. Comments are expensive, not only to write but also to maintain. Therefore comments need to be accurate, brief, and to the point.

Organization refers to the formatting of the code. Good organization provides clues to the logic of a program. Some of the techniques of good organization include: group related topics together; use alignment, white space, blank lines, indentation, blocks; use parentheses to clarify how expressions are evaluated; use a minimum of nesting; be consistent throughout the whole project; make the code easy to read and maintain. The purpose of organization is to make the visual structure match the logical structure of the code.

VALIDATION

The FDA's definition of process validation^[6] is: "Establishing documented evidence that provides a high degree of assurance that a specific process will consistently produce a product meeting its predetermined specifications and quality attributes."

Every company needs to establish a checklist of validation procedures that reflect the principles of the FDA's requirements. Validation is making sure that the code does what it purports to do and that it is stable and reliable. The emphasis is on documentation. If there is no written document, there is no proof of validation. The validation procedures have to be understood and followed.

Validation is costly and is potentially endless. Good programming practice at every development step is essential to ensure high quality, regardless of the amount of final testing and inspection. It is hard to define what constitutes meaningful validation, but here are some ways to produce bug-free code:

1. Design programs to include debugging aids during the development phase and to exclude debugging aids during the production phase.
2. Test every step of programming logic.

3. Try out various data scenarios.
4. Create test data with errors to see if the code breaks down.
5. Devise a group review and change control process.
6. Thoroughly review initial program development and changes.
7. Conduct independent testing.

Most of the testing procedures can prove only the presence, but not the absence, of bugs. Doing a combination of various validation approaches increases the chances of finding bugs. If budget and resources are limited, fixing problems is more important than fixing symptoms. All the test results, the comments from table and listing review by statisticians, data coordinators, clinicians, medical writers, and the regulatory group need to be kept as proofs of validation.

SECURITY PLAN

Many factors can contaminate a program. A computer virus can alter the behavior of a program. A person can accidentally delete or modify the wrong program. Power failure may cause loss of information. A disk may crash. A hard drive may be accidentally reformatted.

Most companies have standard operating procedures (SOPs) for storage, archival, and retrieval. The keys are to have appropriate antivirus software and procedures in place, to have password authentication or audit trail controls, to periodically backup, to have off-site storage, to test the backup recovery procedures, and to have contingency plans for conducting the studies in the event of disasters.

KEEPING UPDATED

Programming is a fast-paced occupation. The SAS software and other application software frequently come out with updated versions with new and improved features. Keeping updated with the technology enhancements not only helps to streamline programming but also allows greater access to certain statistics, better control of output, more appealing presentation of results, and easier data access and information sharing across environment.

It is also necessary to keep up with the FDA's ongoing efforts to improve the review process. Some of the major efforts are *standardized* electronic submissions, the adoption of universal file formats such as using Adobe Acrobat software for transferring documents across platforms, or using Extensible Markup Language (XML) for sharing information and moving data among diverse computer types and operating systems. CDISC (Clinical Data Interchange Standards Consortium) standards have

been recommended for FDA regulatory submissions since 2004 and continue to be developed and improved over time. CDISC provides global consensus-based standards from data collection (CDASH) to submissions with Study Data Tabulation Model (SDTM) or Analysis Data Model (ADaM) as well as metadata for preparing define.xml (CRT-DDS). Thanks to CDSIC standards, programming code can be made more re-usable and validation by double-programming becomes easier.

The Windows point-and-click or drag-and-drop environment makes programming easier and provides multiple options to perform the same task. At the same time, programming can be more error-prone in such environment. A single movement of the mouse button can delete a whole directory. It is crucial to select the correct variables and the correct directory and to define standards common to all programmers. For dynamic reports or graphs, make sure they always reflect the most current data available. Here are the important steps for building an application in an interactive Windows environment:

1. Determine the variables and valid ranges for variable values.
2. Determine the necessary sequences.
3. Group the sequences according to function.
4. Use descriptive labels, icons, pushbuttons, or other graphical elements.
5. Maintain internal consistency in the interface design, work with users to make the interface user-friendly, and work with other applications programmers to jointly set up design standards.
6. Make sure numeric and logical operations are correct.
7. Test the individual sequences.
8. Link the sequences and test the entire application.
9. Add code to capture errors and make a graceful exit instead of letting the application crash.
10. Document the application.

PROGRAMMING ETIQUETTE ON A SHARED PROJECT

Beyond good coding disciplines, the remaining programming virtue is attitude. Programmers usually share different aspects or different studies of programming a clinical trial. A cooperative and understanding attitude facilitates the sound and speedy completion of a project.

Standards and conventions are communication tools. Abide by the CDISC standards and company conventions so the whole team speaks a common language. Write readable, easily shared, and re-usable code whenever possible, keeping in mind that others may have to maintain, modify, or validate the code. Clean up test programs, or

stack the most recent test on top of the previous ones in the same program, and comment out the previous tests. Putting all test programs in one file not only makes the programming area cleaner; it also makes it easy to locate previous tests.

Make the project a good learning experience for everyone. Be tolerant of individual approaches, keep an open mind, and learn from one another. To err is human. We learn not only from good programming tips and techniques but also from making mistakes.

CONCLUSION

In programming, the chain is only as strong as its weakest link, so make good programming practice a habit.

Good Statistics Practice (GSP)

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

The purpose of good statistics practice is not only to minimize bias but also to minimize variability that may occur before, during, and after the conduct of the studies. This entry discusses the role of statistics in drug development and their importance in ensuring the effectiveness and safety of a new drug.

INTRODUCTION

Good statistics practice (GSP) in pharmaceutical research and development is defined as a set of statistical principles and/or standard operating procedures for the best biopharmaceutical practices in design, conduct, analysis, evaluation, reporting, and interpretation of studies at various stages of pharmaceutical research and development.^[1–3] The purpose of GSP is not only to minimize bias but also to minimize variability that may occur before, during, and after the conduct of the studies. More importantly, GSP provides a valid and fair assessment of the drug product under study. The concept of GSP in drug research and development can be seen in many regulatory requirements, standards/specifications, and guidelines/guidances set by most health authorities, such as the U.S. Food and Drug Administration (FDA) and the Committee for Proprietary Medicinal Products (CPMP) in the European Community.^[4] For example, the U.S. regulatory requirements for drug research and development are codified in the U.S. Code of Federal Regulations (CFR), while the U.S. Pharmacopeia and National Formulary (USP/NF) includes standard procedures, test and sampling plans, and acceptance criteria and specifications of many pharmaceutical compounds. In addition, the FDA also develops a number of guidelines and guidances to assist the sponsors in drug research and development. These guidelines and guidances are considered gold standards for achieving good laboratory practice (GLP), good clinical practice (GCP), current good manufacturing practice (cGMP), and good regulatory practice (GRP). The concept of GSP is well outlined in the guideline on *Statistical Principles for Clinical Trials* recently issued by the International Conference on Harmonization.^[5] As a result, GSP not only provides accuracy and reliability of the results derived from the studies, but also ensures the validity and integrity of the studies. Note that in February 2005, the statistical Program Committee (CPE) of European Community adopted the European Statistics Code of good practice and undertook to observe the fifteen principles for GSP in Europe.

ROLE OF STATISTICS IN DRUG DEVELOPMENT

In the research and development of a drug product, statistics are necessarily applied at various critical stages to meet regulatory requirements for the effectiveness, safety, identity, strength, quality, purity, and stability of the drug product under investigation. These critical stages include pre-IND (investigational new drug application), IND, NDA (new drug application), and post-NDA. The roles of statistics at these critical stages are briefly described later.

At the very early stages of pre-IND, pharmaceutical scientists may have to screen thousands of potential compounds in order to identify a few promising compounds. An appropriate use of statistics with efficient screening and/or optimal designs will assist pharmaceutical scientists to identify the promising compounds within a relatively short time frame and cost effectively.

As indicated by the FDA, an IND should contain information regarding chemistry, manufacturing, and controls (CMC) of the drug substance and drug product to ensure the drug identity, strength, quality, and purity of the investigational drug. In addition, the sponsors are required to provide adequate information about pharmacological studies for absorption, distribution, metabolism, and excretion (ADME) and acute, sub-acute, and chronic toxicological studies and reproductive tests in various animal species to show that the investigational drug is reasonably safe to be evaluated in clinical trials in humans. At this stage, statistics are usually applied to (i) validate a developed analytical method, (ii) establish a drug expiration dating period through stability studies, and (iii) assess toxicity through animal studies. Statistics are necessarily applied to meet standards of accuracy and reliability.

Before the drug can be approved, the FDA requires that substantial evidence of the effectiveness and safety of the drug be provided in the Technical Section of Statistics of an NDA submission. Because the validity of statistical inference regarding the effectiveness and safety of the drug is always a concern, it is suggested that a careful review be

performed to ensure an accurate and reliable assessment of the drug product. In addition, to have a fair assessment, the FDA also establishes advisory committees, each consisting of clinical, pharmacological, and statistical experts and one advocate (not employed by the FDA) in designated drug classes and subspecialties to provide a second but independent review of the submission. The responsibility of the statistical expert is not only to ensure that a valid design is used but also to evaluate whether statistical methods used are appropriate for addressing the scientific and medical questions regarding the effectiveness and safety of the drug.

After the drug is approved, the FDA also requires that the drug product be tested for its identity, strength, quality, and purity before it can be released for use. For this purpose, the current good manufacturing practice is necessarily implemented to (i) validate the manufacturing process, (ii) monitor the performance of the manufacturing process, and (iii) provide quality assurance of the final product. At each stage of the manufacturing process, the FDA requires that sampling plans, acceptance criteria, and valid statistical analyses be performed for the intended tests, such as potency, content uniformity, and dissolution.^[6] For each test, sampling plan, acceptance criteria, and valid statistical analysis are crucial for determining whether the drug product passes the test based on the results from a representative sample.

STATISTICAL PRINCIPLES

In this section we will discuss some key statistical principles in the design and analysis of studies that may be encountered at various stages of drug development.

Bias and Variability

For approval of a drug product, regulatory agencies usually require that the results of the studies conducted at various stages of drug research and development are accurate and reliable to provide a valid and fair assessment of the treatment effect. The accuracy and reliability are usually referred to as the *closeness* and the *degree of closeness* of the results to the true value (i.e., true treatment effect). Any deviation from the true value is considered a bias, which may be due to selection, observation, or statistical procedures. Pharmaceutical scientists would make any attempt to avoid bias, whenever possible, to ensure that the collected results are accurate.

The reliability of a study is an assessment of the precision of the study, which measures the degree of the closeness of the results to the true value. The reliability reflects the ability to repeat or reproduce similar outcomes in the targeted population. The higher precision a study is, the more likely it is that the results would be reproducible. The precision of a study can be characterized by the variability incurred during the conduct of the study.

In practice, because studies are usually planned, designed, executed, analyzed, and reported by a team that consists of pharmaceutical scientists from different disciplines, bias and variability inevitably occur. Possible sources of bias and variability should be identified at the planning stage of the study not only to reduce the bias but also to minimize the variability.

Confounding and Interaction

In drug research and development, there are many sources of variation that have an impact on the evaluation of the treatment. If these variations are not identified and properly controlled, then they may be mixed up with the treatment effect that the studies are intended to demonstrate. In this case, the treatment is said to be confounded with the effects due to these variations. For a better understanding, consider the following example. Last winter, Dr. Smith noticed that the temperature at the emergency room was relatively low, which had caused some discomfort among medical personnel and patients. Dr. Smith suspected that the heating system might not function properly and decided to improve it. As a result, the temperature of the emergency room has been raised to a comfortable level this winter. However, this winter is not cold as last winter. Therefore, it is not clear whether the improvement of emergency room temperature was due to the improvement of the heating system or the effect of a warmer winter.

The statistical interaction is to investigate whether the joint contribution of two or more factors is the same as the sum of the contributions from each factor when considered alone. If an interaction between factors exists, an overall assessment cannot be made. For example, suppose that a placebo-controlled clinical trial was conducted at two study centers to assess the effectiveness and safety of a newly developed drug product. Suppose that the results turned out that the drug is efficacious (better than placebo) at one study center and inefficacious (worse than placebo) at the other study center. As a result, a significant interaction between treatment and study center occurred. In this case, an overall assessment of the effectiveness of the drug product can be made.

In practice, possible confounding factors should be identified and properly controlled at the planning stage of the studies. When significant interactions among factors are observed, subgroup analyses may be necessary for a careful evaluation of the treatment effect.

Type I Error, Significance Level, and Power

In statistical analysis, two different kinds of mistakes are commonly encountered when performing hypotheses testing. For example, suppose that a physician is to determine whether or not one of his or her patients is still alive. If the patient is dead, then the physician may remove his or her life support equipment for other patients who need it.

Therefore, the null hypothesis of interest is that the patient is still alive, whereas the alternative hypothesis is that the patient is dead. Under these hypotheses, the physician may make two mistakes, which are (i) he or she may conclude that the patient is dead when in fact the patient is still alive, and (ii) he or she may claim that the patient is still alive when in fact the patient is dead. The first kind of mistake is usually referred as a type I error; the latter is the so-called type II error. Since a type I error is usually considered more important or serious, we would like to limit the probability of committing this kind of error to an acceptable level. This acceptable level of probability of committing a type I error is known as the *significance level*. As a result, if the probability of observing a type I error based on the data is less than the significance level, we conclude that a statistically significant result is observed. A statistically significant result suggests that the null hypothesis be rejected in favor of the alternative hypothesis. The probability of observing a type I error is usually referred to as the *p*-value of the test. On the other hand, the probability of committing a type II error subtracted from 1 is called the *power* of the test. In our example, the power of the test is the probability of correctly concluding the death of the patient when the patient is dead.

For the pharmaceutical application, suppose that a pharmaceutical company is interested in demonstrating that newly developed drug is efficacious. The null hypothesis is often chosen, as the drug is inefficacious, versus the alternative hypothesis that the drug is efficacious. The objective is to reject the null hypothesis in favor of the alternative hypothesis and consequently to conclude that the drug is efficacious. Under the null hypothesis, a type I error is made if we conclude that the drug is efficacious when in fact it is not. This error is also known as *consumer's risk*. Similarly, a type II error is committed if we conclude that the drug is inefficacious. This error is sometimes called *producer's risk*. The power is then considered to be the probability of correctly concluding that the drug is efficacious, when in fact it is. For assessment of drug effectiveness and safety, a sufficient sample size is often selected to have a desired power with a pre-specified significance level. The purpose is to control both type I (significance level) and type II (power) errors.

Randomization

Statistical inference on a parameter of interest of a population under study is usually derived under the probability structure of the parameter. The probability structure depends upon the randomization method employed in sampling. The failure of the randomization will have a negative impact on the validity of the probability structure. Consequently, the validity, accuracy, and reliability of the resulting statistical inference of the parameter is questionable. Therefore, the randomization should be performed using an appropriate randomization method under a valid

randomization model according to the study design to ensure the validity, accuracy, and reliability of the derived statistical inference.

Sample Size Determination/Justification

One of the major objectives of most studies during drug research and development is to determine whether the drug is effective and safe. During the planning stage of a study, the following questions are of particular interest to the pharmaceutical scientists: (i) How many subjects are needed in order to have a desired power for detecting a meaningful difference? (ii) What is the tradeoff if only a small number of subjects are available for the study due to a limited budget and/or some scientific considerations? To address these questions, a statistical evaluation for sample size determination/justification is often employed. Sample size determination usually involves the calculation of sample size for some desired statistical properties, such as power or precision; sample size justification is to provide statistical justification for a selected sample size, which is often a small number.

For a given study, sample size can be determined/justified based on some criteria of a type I error (a desired precision) or a type II error (a desired power). The disadvantage for sample size determination/justification based on the criteria of precision is that it may have a small chance of detecting a true difference. As a result, sample size determination/justification based on the criteria of power becomes the most commonly used method. Sample size is selected to have a desired power for detection of a meaningful difference at a pre-specified level of significance.

In practice, however, it is not uncommon to observe discrepancies among study objective (hypotheses), study design, statistical analysis (test statistic), and sample size calculation. These inconsistencies often result in (i) the wrong test for the right hypotheses, (ii) the right test for the wrong hypotheses, (iii) the wrong test for the wrong hypotheses, or (iv) the right test for the right hypotheses with insufficient power. Therefore, before the sample size can be determined, it is suggested that the following be carefully considered: (i) the study objective or the hypotheses of interest should be clearly stated, (ii) a valid design with appropriate statistical tests should be used, and (iii) sample size should be determined based on the test for the hypotheses of interest.

Statistical Difference and Scientific Difference

A *statistical difference* is defined as a difference that is unlikely to occur by chance alone, while a *scientific difference* is a difference that is considered to be of scientific importance. A statistical difference is also referred to as a *statistically significant difference*. The difference between the concepts of *statistical difference* and *scientific*

difference is that statistical difference involves chance (probability) while scientific difference does not. When we claim there is a statistical difference, the difference is reproducible with a high probability.

When conducting a study, there are basically four possible outcomes. The result may show that (i) the difference is both statistically and scientifically significant, (ii) there is a statistically significant difference yet the difference is not scientifically significant, (iii) the difference is scientifically significant yet it is not statistically significant, and (iv) the difference is neither statistically significant nor scientifically significant.

If the difference is both statistically and scientifically significant or it is neither statistically or scientifically significant, then there is no confusion. However, in many cases, a statistically significant difference does not agree with the scientifically significant difference. This inconsistency has created confusion/arguments among pharmaceutical scientists and biostatisticians. The inconsistency may be due to large variability and/or insufficient sample size.

One-Sided Test versus Two-Sided Test

For the evaluation of a drug product, the null hypothesis of interest is often that there is no difference. The alternative hypothesis is usually that there is a difference. The statistical test for this setting is called a two-sided test. In some cases, the pharmaceutical scientist may test the null hypothesis of no difference against the alternative hypothesis that the drug is superior to the placebo. The statistical test for this setting is known as a *one-sided test*.

For a given study, if a two-sided test is employed at the significance level of 5%, then the level of proof required is one out of 40. In other words, at the 5% level of significance, there is 2.5% chance (or 1 out of 40) that we may reject the null hypothesis of no difference in the positive direction and conclude that the drug is effective at one side. On the other hand, if a one-sided test is used, the level of proof required is 1 out of 20. It turns out that a one-sided test allows more ineffective drugs to be approved because of chance as compared to the two-sided test. It should be noted that when testing at the 5% level of significance with 80% power, the sample size required increases by 27% for a two-sided test as compared to a one-sided test. As a result, there is a substantial cost saving if a one-sided test is used.

However, agreement is not universal among regulatory entities, academia, and the pharmaceutical industry as to whether a one-sided test or a two-sided test should be used. The U.S. Food and Drug Administration tends to oppose the use of a one-sided test, though this position has been challenged by several pharmaceutical companies on Drug Efficacy Study Implementation (DESI) drugs at the Administrative Hearing. Dubey^[7] has pointed out that several viewpoints that favor the use of one-sided tests were discussed in an administrative hearing. These points indicated that a one-sided test is appropriate in the following

situations: (i) where there is truly concern with outcomes in one tail only, and (ii) where it is completely inconceivable that the results could go in the opposite direction.

European Statistics Code of Good Practice

In February 2005, the Statistical Program Committee (CPE) adopted the European Statistics Code of Good Practice and undertook to observe the 15 principles established therein, as well as to periodically review their application using the good practice indicators corresponding to each of the 15 principles. This code has been embraced by *Instituto Nacional de Estadística* (INE) by way of a resolution by the Board of Directors, which thus undertakes to comply with the aforementioned when establishing the general principles regulating the generating of statistics for State purposes. In this way, INE endeavors to guarantee an improvement in the service it provides to society, which will undoubtedly reinforce its image as an institution. In May 2005, the CPE agreed a formula for monitoring implementation of the code for a duration of three years. During that period, the various countries must carry out quality self-assessment, taking as a reference the aforementioned good practice indicators, which in turn must be contrasted and checked via so-called peer reviews. The end result was submitted to the Board and to the European Parliament in 2008. The 15 principles are briefly described below:

- Principle 1: Professional Independence—The professional independence of statistical authorities from other policy, regulatory, or administrative departments and bodies, as well as from private sector operators, ensures the credibility of European statistics.
- Principle 2: Mandate for data collection—Statistical authorities must have a clear legal mandate to collect information for European statistical purposes. Administrations, enterprises, and households and the public at large may be compelled by law to allow access to or deliver data for European statistical purposes at the request of statistical authorities.
- Principle 3: Adequacy of resources—The resources available to statistical authorities must be sufficient to meet European statistics requirements.
- Principle 4: Quality commitment—All ESS members commit themselves to work and cooperate according to the principles fixed in the “Quality declaration of the European statistical system.”
- Principle 5: Statistical confidentiality—The privacy of data providers (households, enterprises, administrations, and other respondents),

- the confidentiality of the information they provide, and its use only for statistical purposes must be absolutely guaranteed.
- Principle 6: Impartiality and objectivity—Statistical authorities must produce and disseminate European statistics respecting scientific independence and in an objective, professional, and transparent manner in which all users are treated equitably.
- Principle 7: Sound methodology—Sound methodology must underpin quality statistics. This requires adequate tools, procedures, and expertise.
- Principle 8: Appropriate statistical procedures—Appropriate statistical procedures, implemented from data collection to data validation, must underpin quality statistics.
- Principle 9: Non-excessive burden on respondents—The reporting burden should be proportionate to the needs of the users and should not be excessive for respondents. The statistical authority monitors the response burden and sets targets for its reduction overtime.
- Principle 10: Cost-effectiveness—Resources must be effectively used.
- Principle 11: Relevance—European statistics must meet the needs of users.
- Principle 12: Accuracy and reliability—European statistics must accurately and reliably portray reality.
- Principle 13: Timeliness and punctuality—European statistics must be disseminated in a timely and punctual manner.
- Principle 14: Coherence and comparability—European statistics should be consistent internally and over time and comparable among regions and countries; it should be possible to combine and make joint use of related data from different sources.
- Principle 15: Accessibility and clarity—European statistics should be presented in a clear and understandable form, disseminated in a suitable and convenient manner, and available and accessible on an impartial basis with supporting metadata and guidance.

IMPLEMENTATION OF GSP

The implementation of GSP in drug research and development is a team project that requires mutual communication, confidence, respect, and cooperation among statisticians, pharmaceutical scientists in the related areas, and regulatory agents. The implementation of GSP

involves some key factors that have an impact on the success of GSP. These factors include (i) regulatory requirements for statistics, (ii) the dissemination of the concept of statistics, (iii) appropriate use of statistics, (iv) effective communication and flexibility, and (v) statistical training. These factors are briefly described next.

In the drug development and approval process, regulatory requirements for statistics are the key to the implementation of GSP. They not only enforce the use of statistics but also establish standards for statistical evaluation of the drug products under investigation. An unbiased statistical evaluation helps pharmaceutical scientists and regulatory agents in determining (i) whether the drug product has the claimed effectiveness and safety for the intended disease, and (ii) whether drug product possesses good drug characteristics, such as the proper identity, strength, quality, purity, and stability. A set of guideline standard operating procedures is often developed to fulfill with regulatory requirements for good statistics practice. For example, Spriet and Dupin-Spriet^[1] have proposed a set of procedures to fulfill quality requirements set by company policy according to regulatory requirements of good clinical practice. Wiles et al.^[2] have indicated that the Professional Standards Working Party of the Statisticians in the Pharmaceutical Industry (PSI) in the United Kingdom has developed a set of guideline standard operating procedures for good statistics practice. These guideline standard operating procedures cover clinical development plan, clinical trial protocol, statistical analysis plan, determination of evaluability of subjects for analysis, randomization and blinding procedure, data management, interim analysis plan, statistical report, archiving and documentation, data overview, and quality assurance and quality control.

In addition to regulatory requirements, it is always helpful to disseminate the concept of statistical principles described earlier whenever possible. It is important for pharmaceutical scientists and regulatory agents to recognize that (i) a valid statistical inference is necessary to provide a fair assessment with certain assurance regarding the uncertainty of the drug product under investigation, (ii) an invalid design and analysis may result in a misleading or wrong conclusion about the drug product, and (iii) a larger sample size is often required to increase the statistical power and precision of the studies. The dissemination of the concept of statistics is critical to establish the pharmaceutical scientists' and regulatory agents' brief in statistics for scientific excellence.

One of the commonly encountered problems in drug research and development is the misuse or abuse of statistics in some studies. The misuse or abuse of statistics is a critical issue that may result either in having the right question with the wrong answer or in having the right answer for the wrong question. For example, for a given study, suppose that a right set of hypotheses (the right question) is established to reflect the study objective. A misused statistical test may provide a misleading or wrong answer to the right question. On the other hand, in many clinical trials,

point hypotheses for equality (the wrong question) are often wrongly used for establishment of equivalency. In this case, we have the right answer (for equality) for the wrong question. As a result, it is recommended that appropriate statistical methods be chosen to reflect the design that should be able to address the scientific or medical questions regarding the intended study objectives for implementation of GSP.

Communication and flexibility are important factors to the success of GSP. Inefficient communication between statisticians and pharmaceutical scientists or regulatory agents may result in a misunderstanding of the intended study objectives and consequently in an invalid design and/or inappropriate statistical methods. Thus, effective communication among statisticians, pharmaceutical scientists, and regulatory agents is essential for the implementation of GSP. In addition, in many studies, the assumption of a statistical design or model may not be met, due to the nature of the drug product under investigation, the experimental environment, and/or other causes related/unrelated to the studies. In this case, the traditional approach of doing everything by the book does not help. In practice, since a concern from a pharmaceutical scientist or the regulatory agent may translate into a constraint for a valid statistical design and appropriate statistical analysis, it is suggested that a flexible yet innovative solution be developed under the constraints for the implementation of GSP.

Because regulatory requirements for the drug development and approval process vary from drug to drug and from country to country, various designs and/or statistical methods are often required for a valid assessment of a drug product. Therefore, statistical continued/advanced education and training programs should be routinely held for both statisticians and non-statisticians, including pharmaceutical scientists and regulatory agents. The purpose of such a continued/advanced education and/or training program is threefold. First, education and training enhance communications within the statistical community. Statisticians can certainly benefit from such a training and/or educational program by acquiring more practical experience and knowledge. In addition, education and training provide the opportunity to share/exchange information, ideas, and/or concepts regarding drug development between professional societies. Finally, education and training identify critical practical and/or regulatory issues that are commonly encountered in the drug development and regulatory approval process. A panel discussion from different disciplines may result in some consensus to resolve the issues, which helps in establishing standards of statistical principles for the implementation of GSP.

CONCLUSION

During the development and regulatory approval process, good pharmaceutical practices are necessarily implemented (i) to ensure the effectiveness and safety of the drug product under investigation before approval and (ii) to ensure that the drug product possesses good drug characteristics, such as the proper identity, strength, quality, purity, and stability, in compliance with the standards as specified in the USP/NF after regulatory approval. These good pharmaceutical practices include GLP for animal studies, GCP for clinical development, cGMP for chemistry, manufacturing, and controls (CMC), and GRP for regulatory review and approval process. In essence, GSP is the foundation of GLP, GCP, cGMP, and GRP. The implementation of GSP is a team project that involves statisticians, pharmaceutical scientists, and regulatory agents as well. The success of GSP depends upon mutual communication, confidence, respect, and cooperation among statisticians, pharmaceutical scientists, and regulatory agents.

Good Validation Practice (GVP)

Ying Geng and Lan He

National Institutes for Food and Drug Control, Beijing, China

Abstract

Validation practice in the pharmaceutical industry is indispensable for quality assurance and quality control. It confirms that the facility, process, operating system, analytical method, or product meets its intended use. Therefore, it assures the quality of pharmaceutical manufacture and the justification of analytical results. This article first presents the definition of validation in pharmaceutical industry, and then summarizes good validation practice on two basic ranges, process validation and analytical method validation, from regulated requirement, quality-by-design concept, and technology transfer perspectives. The statistical justification of pharmaceutical validation plays an important role for its valid and fair assessment.

Keywords: Analytical life cycle; Analytical method validation; Pharmaceutical validation; Process validation; Quality by design; Technology transfer.

INTRODUCTION

Validation practice in the pharmaceutical industry is indispensable for quality assurance and quality control. It confirms that the facility, process, operating system, analytical method, or product meets its intended use. Therefore, it assures the quality of pharmaceutical manufacture and the justification of analytical results. Good validation practice regulates the pharmaceutical validation practice with scientific principles and/or standard operating procedures for the validation practices in design, conduct, monitoring, evaluation, reporting, and decision-making in pharmaceutical manufacturing and regulatory registration. Statistics plays an important role for the validation practice for it provides scientific tools for valid design and fair assessment.

This article first presents the definition of the validation in pharmaceutical industry, and then summarizes good validation practice on two basic ranges, process validation and analytical method validation, from regulated requirement, quality-by-design (QbD) concept, and technology transfer (TT) perspectives. Finally, the important role that statistics plays is highlighted.

DEFINITION OF VALIDATION IN THE PHARMACEUTICAL INDUSTRY

In pharmaceutical industry, the objective of validation is to ensure that the drug product meet specification for identity, strength, quality, purity, stability and reproducibility. The concept of validation was introduced firstly by

Ted Byers and Bud Loftus, in order to improve the quality of pharmaceutical products.^[1] Generally, the definition of validation was described by subpart H part 820 in CRF 21 for Chapter I, food and drug administration, as “Validation means confirmation by examination and provision of objective evidence that the particular requirements for a specific intended use can be consistently fulfilled.”^[2] Two more specific definitions were described in CRF 21, one as “establishing documented evidence that provides a high degree of assurance that a system will consistently produce a product meeting its predetermined specifications and quality characteristics” in subpart B of part 106 for cGMP,^[3] and the other as “obtaining and evaluating scientific and technical evidence that a control measure, combination of control measures, or the food safety plan as a whole, when properly implemented, is capable of effectively controlling the identified hazards”.^[4]

Under the general definition of validation, validation practice can refer to people, equipment, facility, method, process, or other concerns covered in the Current Good Manufacturing Practice (cGMP); the FDA published a cluster of guidelines regulating the validation practices varying from analytical method validation (AMV)^[5,6] and process validation (PV)^[7] to the sterilization PV,^[8] software validation,^[9] computer system validation,^[10] as well as clinical validation.^[11] Basically, pharmaceutical validations include AMV for the purpose that the validation of an analytical method or a test procedure is to assure the accuracy and reliability of the test results, and PV, which is aiming to assure that the final product has a high probability of meeting the standards for the identity, strength, quality, purity, stability, and reproducibility of the drug product.^[12]

PV OF PHARMACEUTICAL INDUSTRY

Process validation began from the validation of sterile process in the 1970s. With several decades of development, the process validation evolved into a wide range of processes in the pharmaceutical industry, such as aseptic process for bulk pharmaceutical chemicals, container preparation processes, lyophilization process, biotechnology process, solid dosage forms process, and packaging process.

Regulated Requirement

The cGMP regulations in 21 Code of Federal Regulations (CFR) Parts 210 and 211 described general and specific requirements for validation of manufacturing process, which are mainly on designing, operating, and controlling a process, to assure the product quality. The FDA published an updated “Guidance for Industry Process Validation: General Principles and Practices” in January 2011,^[7] replacing “Guideline on General Principles of Process Validation” (the 1987 Guidance).^[13] In the 2011 Guidance, PV is defined as “the collection and evaluation of data, from the process design stage through commercial production, which establishes scientific evidence that a process is capable of consistently delivering quality product,” and described in three stages^[7]:

- Stage 1—Process design: the commercial manufacturing process is defined during this stage based on knowledge gained through development and scale-up activities.
- Stage 2—Process qualification: the process design is evaluated to determine if the process is capable of reproducible commercial manufacturing.
- Stage 3—Continued process verification: ongoing assurance is gained during routine production that the process remains in a state of control.

As stated in the guideline 2011,^[7] Effective PV contributes significantly to assuring drug quality. The basic principle of quality assurance is that a drug should be produced that is fit for its intended use. This principle incorporates the understanding that the following conditions exist:

- a. Quality, safety, and efficacy are designed or built into the product.
- b. Quality cannot be adequately assured merely by in-process and finished product inspection or testing.
- c. Each step of a manufacturing process is controlled to assure that the finished product meets all quality attributes including specifications.

QbD Quality-by-Design Concept and PV

Since the FDA began with the initiative entitled “Pharmaceutical Quality for the 21st Century” in 2002,^[14] new

technological advances, modern quality management techniques, and risk-based approaches have been encouraged into adoption in the pharmaceutical industry. The International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) developed a series of guidance, Q8 Guideline Pharmaceutical Development,^[15] Q9 guideline Quality Risk Management,^[16] and Q10 Pharmaceutical Quality System.^[17] The “Guidance for Industry Process Validation: General Principles and Practices (Guideline 2011)” aligns PV activities with a product life cycle concept and risk management. QbD uses a science and risk-based approach that emphasizes the importance of developing scientific knowledge and thorough understanding of both the product and the process.

TT of Pharmaceutical Process

TT of pharmaceutical process refers to the transfer of a manufacturing process from one site to another site. TT could be from an early-stage research laboratory to a manufacture site, between two clinical manufacture sites, from one clinical manufacture site to commercial site, or between commercial sites, and be with the same scale or a scale-up strategy. A successful TT requires a comprehensive knowledge of process characteristics to demonstrate that the transferred product meet in-process release and stability specifications, and be consistent and reproducible with the donor site. The prospective validation with QbD approach may be applied to identify critical process parameters that may have impacts on critical quality attributes. Moreover, gap analysis and risk assessment may be utilized for the purpose of quality risk management and understanding the operation differences between the donor and receiving sites.

VALIDATION OF ANALYTICAL PROCEDURES

Good Analytical Method Validation Practice ensures accurate and reliable test results, and therefore the safety and quality of the product.^[18]

Regulated Requirement

In the United States, the Federal Food, Drug, and Cosmetic Act regulated that assays and specifications in monographs of the United States Pharmacopeia and the National Formulary (USP–NF) constitute legal standards. The cGMP regulations 21 CFR 211.194(a) require that test methods, “which are used for assessing compliance of pharmaceutical articles with established specifications, must meet proper standards of accuracy and reliability.”^[19] Similar regulations for the regulation of analytical procedure validation as part of registration application and newly carried in pharmacopoeia were drafted in various compendia of

the United States,^[20] the European Union,^[21] Japan,^[22] and China.^[23] The ICH also published harmonized guideline in order to provide some guidance and recommendations for analytical procedure.^[24,25]

Harmonized Characteristics

As harmonized by ICH, during the validation of analytical procedures, appropriated validation characteristics can be considered simultaneously to provide a sound, overall knowledge of the capabilities of the analytical procedure.^[24] These validation characteristics are accuracy, precision (repeatability, intermediate precision, and reproducibility), specificity, detection limit, quantitation limit linearity, and robustness. There are four common types of analytical procedure: (1) identification tests, (2) quantitative tests for impurities' content, (3) limit tests for the control of impurities, and (4) quantitative tests for active moiety in samples of drug substance or drug product or other selected component(s) in the drug product.^[25]

Assay validation is the process of demonstrating and documenting that the performance characteristics of the procedure and its underlying method meet the requirements for the intended application and that the assay is therefore suitable for its intended use. Biological assays (bioassays) typically exhibit greater variability than chemically based tests, for the inherent characteristics of biological response to the product; a biochemical or physiological response at the cellular level; enzymatic reaction rates or biological responses induced by immunological interactions; or ligand and receptor binding.^[26,27] Therefore, unlike the straightforward validation strategy for well-characterized, chemically based small-molecule drug product, the validation of bioassays is more flexible and requires more profound statistical consideration.

Analytical Life Cycle and Method Transfer

In 2010, Nethercote et al. suggested that AMV can benefit from a life cycle approach and proposed that method validation be defined as “the collection and evaluation of data and knowledge from the method design stage through its life cycle of use which establishes scientific evidence that a method is capable of consistently delivering quality data.”^[28] The USP general chapter <1224> describes the transfer of analytical procedure (also referred to as method transfer) as “the documented process that qualifies a laboratory (the receiving unit) to use an analytical test procedure that originate in another laboratory (the transferring unit), thus ensuring that the receiving unit has the procedural knowledge and ability to perform the transferred analytical procedure as intended.”^[29] Under the concept of life cycle, method transfer may be conducted at any stage from the initializing site (originator) to either another internal site(s) or an external receiving laboratory (recipient). The principle goal of method transfer is to

demonstrate that the method is appropriately transferred and validated at the receiving laboratory.

STATISTICS AND GOOD VALIDATION PRACTICE

Statistics is deeply involved in pharmaceutical validation, from experimental/method design, analytical characteristic evaluation, sampling strategy, quality control, specification setting to process capability/risk assessment. It provides scientific tools for good validation practice, such as risk assessment, process capability control, design of experiment, multiple stages tests approach, and sampling strategy.

Statistics is directly regulated by cGMP guidelines: CFR 21 211.110(b) requires that in-process specifications be “derived from previous acceptable process average and process variability estimates where possible and determined by *the application of suitable statistical procedures* where appropriate,”^[30] and cGMP regulations specify that samples must meet specifications and *statistical quality control criteria* as condition of approval and release (§ 211.165(d)),^[31] and the report must *provide appropriate confidence interval* (§ 870.1415(c)).^[32] Moreover, in the 2011 Guidance, it is recommended that a statistician or a person with adequate training in statistical process control techniques develop the data collection plan and statistical methods and procedures used in measuring and evaluating process stability and process capability. As stated, “The 2011 Guidance references a number of acceptable industry standards but clarifies that manufacturers must make deliberate decisions about which statistical tools and analyses are appropriate for their products and processes.”^[7]

CONCLUSION

Validation is a scientific endeavor at various stages of life cycle of pharmaceutical product development. Since the issue of the Guideline on General Principles of Process Validation (the 1987 Guidance), good validation practices have been broadened to a wide range through pharmaceutical industry. Good validation practices ensure the analytical method is suitable for its intended use throughout the life cycle, the well-designed experiment is conducted, the variation due to process capability is under control, and the products have required quality and reproducibility from regulatory agencies. The adoption of GVP guidelines is inherently an important part of the QbD concept, modernizing the pharmaceutical industry progress and producing high-quality drug products, and is critical for the desired state of under-control pharmaceutical manufacturing and high-quality products without extensive regulation oversight. The statistical justification of pharmaceutical validation plays an important role for its valid and fair assessment.

Group Sequential Methods

Cheng-Tao Chang

Novo Nordisk Inc., Princeton, New Jersey, U.S.A.

Abstract

The group sequential procedure (design, monitoring, and analysis) is the most commonly applied form of sequential procedure to facilitate the conduct of interim analysis in the biopharmaceutical field. The focus of this entry is on the regulatory requirements, statistical methods, and design monitoring of group sequential procedures.

INTRODUCTION

The group sequential procedure (design, monitoring, and analysis) is the most commonly applied form of sequential procedure to facilitate the conduct of interim analysis in the biopharmaceutical field. A primary motivation of a group sequential analysis, in general, is the conservation of experimental materials and/or research effort. An important biopharmaceutical application in this aspect was in drug screening.^[1] Recently, active developments of the group sequential procedure have been in clinical trials, especially trials with mortality or irreversible morbidity as the primary endpoint. In these clinical trials, a further consideration is an ethical obligation to terminate the study at the earliest opportunity to prevent the administration of a less favorable therapy to additional patients. Conducting the clinical trial in stages, with group sizes predetermined by a certain schedule, provides logistical feasibility over fully sequential methods because these experiments or clinical trials generally will involve a lengthy time to respond. Yet the advantage of reducing the average sample number is largely retained.^[2] Many different methods of group sequential procedure are available: different stopping boundaries, different Type I error spending/use functions, conditional power or predictive power approaches, Bayesian methods, etc. The logistics of a group sequential trial are, however, complicated and require careful planning and conducting. A review article is given in Ref. [3], and a rather complete book has been published recently as well.^[4]

REGULATORY REQUIREMENTS

The International Conference on Harmonization (ICH) Guidelines (February 1998)^[5] discuss the regulatory requirements on interim analyses in general (E3, Section 11.4.2.3) and the group sequential procedures in particular regarding data monitoring and early stopping

(E9, Sections 3.4 and 4.1–4.6). The following is a summary:

- All interim analyses should be carefully planned in advance and should be described in the protocol. Any unplanned interim analysis should be avoided if at all possible. In the event that an unplanned interim analysis was conducted, a protocol amendment describing the interim analysis should be completed prior to an unblinded access to treatment comparison data, and the study report should explain why it was necessary and the degree to which the blindness had to be broken, and should provide an assessment of the potential magnitude of bias introduced and of the impact on the interpretation of the results.
- The schedule of analyses, or at least the considerations that will govern its generation, should be stated in the protocol or amendment before the time of the first interim analysis; the stopping guidelines and their properties should also be clearly stated there.
- The procedure plan should be written or approved by the Data Monitoring Committee (DMC), when the trial has one.
- Any changes to the trial and any consequent changes to the statistical procedures should be specified in an amendment to the protocol at the earliest opportunity.
- The procedures selected should always ensure that the overall probability of Type I error is controlled.
- The execution of an interim analysis must be a completely confidential process when unblinded data and results are potentially involved. All staff involved in the conduct of the trial should remain blind to the results of such analyses. Investigators should only be informed about the decision to continue or discontinue the trial, or to implement modifications to trial procedures.
- Any interim analysis planned for administrative purposes only should also be described in the protocol and subsequently reported. The specific purposes

should be clearly stated and should specifically exclude any possibility of early stopping. The blind should not be broken.

STATISTICAL METHODS

Fundamentals

We start by considering the design of a clinical trial with a plan of monitoring the data at calendar time $ct_1, ct_2, \dots, ct_K$ for some fixed $K > 1$. For example, a trial monitoring committee might plan to meet every March 31 and September 30 for the first 2 years and then every June 15 for the rest of the trial duration. (The DMC will be discussed later.) Corresponding to the ct_i , $i = 1, \dots, K$ are the information times (or *information fractions*) $t_1, t_2, \dots, t_K = 1$. (The *information time/fraction* and the *maximum duration trial* vs. *maximum information trial* will be discussed later.) At information time t_i , $i = 1, \dots, K$, standardized Z -statistics $Z_1, Z_2, \dots, Z_K$ are calculated based on the accumulated data for testing hypotheses about the treatment effect represented by a parameter θ . A focal statistical problem of the group sequential procedures is to find critical values to satisfy certain desirable operational characteristics. These critical values are the so-called *group sequential boundaries*. For example, for a one-sided hypothesis with the decision options being “either reject $H_0: \theta = 0$ or continue at the interim stages” and “reject or accept H_0 at the final stage,” the problem is to find values $b_1, b_2, \dots, b_K$ such that the overall Type I error α is maintained at a prespecified level:

$$P_{H_0}(\text{Reject } H_0) = P_{H_0}(Z_1 \geq b_1, \text{ or } Z_2 \geq b_2, \text{ or } \dots Z_K \geq b_K) = \alpha \quad (1)$$

(Different forms of one-side hypotheses are given in Ref. [3].) For a corresponding two-sided hypothesis test, a symmetric boundary would replace α by $\alpha/2$ in Eq. 1 and then apply the one-sided boundary symmetrically. (Asymmetric boundaries and interim analyses with a chance to accept H_0 at an early stage will be discussed later.) In the following, we first review several commonly cited group sequential boundaries.

Equally Spaced Group Sequential Boundaries

Suppose that the (information) times are equally spaced: $t_1 = 1/K$, $t_2 = 2/K, \dots, t_K = K/K = 1$.

- Pocock:^[6] Find $b_i = c$ for $i = 1, \dots, K$ such that:

$$P_{H_0}(Z_1 \geq c, \text{ or } Z_2 \geq c, \text{ or } \dots Z_K \geq c) = \alpha \quad (2)$$

For example, if set $\alpha = 0.025$ and $K = 5$, then $c = 2.413$. The boundaries are (2.413, 2.413, 2.413, 2.413, 2.413).

- O’Brien and Fleming:^[7] Find c such that:

$$P_{H_0}(Z_1 \sqrt{t_1} \geq c, \text{ or } Z_2 \sqrt{t_2} \geq c, \text{ or } \dots Z_K \sqrt{t_K} \geq c) = \alpha \quad (3)$$

For $\alpha = 0.025$ and $K = 5$, $c = 2.04$. Hence $b_i = 2.04/\sqrt{t_i} = 2.04/\sqrt{i/5}$. The boundaries are (4.562, 3.226, 2.634, 2.281, 2.040).

- Haybittle^[8] and Peto et al.^[9] Find $b_i = c$ for $i = 1, \dots, K-1$ such that:

$$P_{H_0}(Z_1 \geq c, \text{ or } Z_2 \geq c, \text{ or } \dots Z_K \geq z_{1-\alpha}) = \alpha \quad (4)$$

For example, if set $\alpha = 0.025$ and $K = 5$, then $c = 3.291$. The boundaries are (3.291, 3.291, 3.291, 3.291, 1.960).

The preceding boundaries, for the two-sided case, are not “closed” at the final analysis. Whitehead and Stratton^[10] and Whitehead and Brunier^[11] proposed “triangular” closed boundaries, which plot the unstandardized test statistic vs. its variance.

The calculations of the boundaries require iterative numerical integrations.^[12,13] Commercial computer packages available for obtaining the boundaries for a variety of K and α include EaSt^[14] and S + ^[15] for the Pocock and O’Brien–Fleming, and PEST^[16] for the Whitehead boundaries. Useful programs and documents are also publicly available on the World Wide Web sites (see Refs. [17,18]).

The choice of the boundaries in the trial design depends on the intention of early stopping of a trial. O’Brien–Fleming boundaries are the most stringent among the three at early times, while Pocock boundaries maintain a constant throughout. Haybittle–Peto boundaries are similar to Pocock boundaries at interim stages but set the final analysis resembling the fixed sample size design.

At the design stage, it may be reasonable to plan for fixed K analyses at equally spaced information times. But when the trial is ongoing (i.e., when monitoring the study), changes often occur. Interim analyses may well not be on the preplanned schedule, and the frequency of the analyses K may also change. This requires a more flexible procedure. The Slud–Wei^[19] and Lan–DeMets^[20] Type I error spending/use function approach meets this need.

Type I Error Spending/Use Function Approach

The idea of the Type I error spending/use function approach can be illustrated as follows. Untie the fixed K in Eq. expression 1 and decompose the rejection region:

$$R = \{Z_1 \geq b_1, \text{ or } Z_2 \geq b_2, \text{ or } Z_3 \geq b_3, \dots\}$$

into disjoint regions:

$$R_1 = \{Z_1 \geq b_1\}$$

$$\begin{aligned}
& \{Z_{t_1} \geq b_1, \text{ or } Z_{t_2} \geq b_2\} \\
&= \{Z_{t_1} \geq b_1\} \cup \{Z_{t_1} < b_1, Z_{t_2} \geq b_2\} = R_1 \cup R_2 \\
& \{Z_{t_1} \geq b_1, \text{ or } Z_{t_2} \geq b_2, \text{ or } Z_{t_3} \geq b_3\} \\
&= (R_1 \cup R_2) \cup \{Z_{t_1} < b_1, Z_{t_2} < b_2, Z_{t_3} \geq b_3\} \\
&= (R_1 \cup R_2) \cup R_3
\end{aligned}$$

and so on. Hence:

$$\begin{aligned}
P_{H_0}(R) &= P_{H_0}(R_1 \cup R_2 \cup R_3 \cup \dots) \\
&= P_{H_0}(R_1) + P_{H_0}(R_2) + P_{H_0}(R_3) + \dots = \alpha
\end{aligned}$$

At t_1 , we specify a value of $\alpha(t_1) = P_{H_0}(R_1)$ and solve for b_1 . At t_2 , specify:

$$\begin{aligned}
\alpha(t_2) &= P_{H_0}(R_1 \cup R_2) = P_{H_0}(R_1) + P_{H_0}(R_2) \\
&= \alpha(t_1) + P_{H_0}(R_2)
\end{aligned}$$

This leads to $P_{H_0}(R_2) = \alpha(t_2) - \alpha(t_1)$, and we can solve for b_2 because b_1 is already known from the first stage. Similarly at t_3 , specify:

$$\begin{aligned}
\alpha(t_3) &= P_{H_0}(R_1 \cup R_2 \cup R_3) = (P_{H_0}(R_1) + P_{H_0}(R_2)) + P_{H_0}(R_3) \\
&= \alpha(t_2) + P_{H_0}(R_3)
\end{aligned}$$

Thus $P_{H_0}(R_3) = \alpha(t_3) - \alpha(t_2)$. We then solve for b_3 because b_1 and b_2 have already been solved in the previous steps. The process continues.

Note that, when solving for b_2 , we only need the joint distribution of (Z_{t_1}, Z_{t_2}) . For a partial sum process with independent increments (see later discussion), where we can write

$$Z_i = \frac{S(t_i)}{\sqrt{I(t_i)}}$$

with the numerator being the cumulative sum of the observations (i.i.d. variates with mean θ) and the denominator being the square root of the cumulative statistical information in estimating θ at time t_i , the correlation is:

$$\begin{aligned}
\rho(t_2, t_2) &= \text{Corr} = \text{Cov}(Z_{t_1}, Z_{t_2}) \\
&= \text{Cov}\left(\frac{S(t_1)}{\sqrt{I(t_1)}}, \frac{S(t_2)}{\sqrt{I(t_2)}}\right) \\
&= \text{Cov}\left(\frac{S(t_1)}{\sqrt{I(t_1)}}, \frac{S(t_1) + (S(t_2) - S(t_1))}{\sqrt{I(t_2)}}\right) \\
&= \frac{1}{\sqrt{I(t_1)I(t_2)}} \text{Var}(S(t_1)) = \sqrt{\frac{I(t_1)}{I(t_2)}}
\end{aligned}$$

Other time point boundaries follow similarly. [When information is proportional to the sample size, then $\rho(t_1, t_2) = (n_1/n_2)^{1/2} = (t_1/t_2)^{1/2}$.] Therefore the joint distribution only involves the ratio of information at the current stage and before, not the later time points. This indicated the flexibility of this approach for monitoring trials because there is no requirement for a given K , the total number of analyses, or for the “equally spaced t_i ” restriction. All that is needed is $\alpha(t_1) < \alpha(t_2) < \dots < \alpha(1) = \alpha$, a strictly increasing function $\alpha(t)$, known as the “Type I error (α) spending/use function” prespecified in the study design protocol.

Example: Two-stage design (one interim and one final analyses) symmetrical boundaries.

Specify the overall Type I error $\alpha = 0.05$ (two-sided test) and the spending function as $\alpha(t) = \alpha t$. Suppose we conduct an interim analysis when $t_1 = 1/2$, then $\alpha(t_1 = 1/2) = 0.025$. The corresponding boundary point at $t_1 = 1/2$ is $b_1 = 2.244$. This leaves $\alpha - \alpha(t_1 = 1/2) = 0.025$ to be spent at the final stage $t_2 = 1$. Solving $P\{|Z_{t_1}| < 2.244, |Z_{t_2}| \geq b_2\} = 0.025$ given that the correlation of the bivariate normal distribution is $t_1/t_2 = 1/2$, we obtain $b_2 = 2.126$. Notice that at the final stage, $\alpha_2 \equiv P(|Z| > 2.126) = 0.034$. That is, with this linear/uniform spending function, if an interim testing is to be conducted in the middle of the trial, the P value at the final stage has to be less than 0.034—instead of the 0.05 level—to be significant.

A natural question is “What kind of α spending function describes the Pocock boundary and the O’Brien–Fleming boundary?”

Example: $K = 5$, $\alpha = 0.025$, Pocock boundary: (2.413, 2.413, 2.413, 2.413, 2.413).

- i. $P_{H_0}(Z_{t_1} \geq 2.413) = 0.0079 \Rightarrow \alpha(t_1 = 1/5) = 0.0079$
- ii. $P_{H_0}(Z_{t_1} \geq 2.413 \text{ or } Z_{t_2} \geq 2.413)$
 $= P_{H_0}(Z_{t_1} \geq 2.413) + P_{H_0}(Z_{t_1} < 2.413, Z_{t_2} \geq 2.413)$
 $= 0.0079 + 0.0059 = 0.0138$
 $\Rightarrow \alpha(t_2 = 2/5) = 0.0138$
- iii. $P_{H_0}(Z_{t_1} \geq 2.413, \text{ or } Z_{t_2} \geq 2.413, \text{ or } Z_{t_3} \geq 2.413) = P_{H_0}(Z_{t_1} \geq 2.413 \text{ or } Z_{t_2} \geq 2.413) + P_{H_0}((Z_{t_1} < 2.413, Z_{t_2} < 2.413), (Z_{t_3} \geq 2.413)) = 0.0138 + 0.0045 = 0.0183$
 $\Rightarrow \alpha(t_3 = 3/5) = 0.0183$
- iv. $P_{H_0}(Z_{t_1} \geq 2.413, \text{ or } Z_{t_2} \geq 2.413, \text{ or } Z_{t_3} \geq 2.413, \text{ or } Z_{t_4} \geq 2.413)$
 $= \dots (\text{similar steps}) = 0.0183 + 0.0036$
 $= 0.0219 \Rightarrow \alpha(t_4 = 4/5) = 0.0219$
- v. $P_{H_0}(Z_{t_1} \geq 2.413, \text{ or } Z_{t_2} \geq 2.413, \text{ or } Z_{t_3} \geq 2.413, \text{ or } Z_{t_4} \geq 2.413, \text{ or } Z_{t_5} \geq 2.413) = \dots (\text{similar steps})$
 $= 0.0219 + 0.0031 = 0.0250 \Rightarrow \alpha(t_5 = 1) = 0.0250$

Example: $K = 5$, $\alpha = 0.025$, O'Brien–Fleming boundary: (4.56, 3.23, 2.63, 2.28, 2.04).

Following similar steps as described previously, we can obtain the (discrete) Type I error spending function $\alpha(t_1 = 1/5) = 0.0000$, $\alpha(t_2 = 2/5) = 0.0006$, $\alpha(t_3 = 3/5) = 0.0045$, $\alpha(t_4 = 4/5) = 0.0128$, and $\alpha(t_5 = 1) = 0.0250$.

Removing the restriction of a fixed K and equally spaced $t_i = i/K$, Lan and DeMets^[20] gave the continuous α spending function for the general Pocock boundary as $\alpha_{\text{Pocock}}(t) = \alpha \ln[1 + (e - 1)t]$, and for the general O'Brien–Fleming boundary as:

$$\alpha_{\text{OB-F}}(t) = 2 \left[1 - \Phi \left(\frac{z_{\alpha/2}}{\sqrt{t}} \right) \right]$$

where $\Phi(\cdot)$ is the c.d.f. of the standard normal variate.

Other Type I error rate spending functions have also been proposed in the literature. Lan and DeMets^[20] and Kim and DeMets^[21] studied a certain member of the “power family” $\alpha(t) = \alpha t^c$, $c > 0$. The landmark clinical trial “Simvastatin Scandinavian Survival Study” or the “4S”^[22] used a member of the “truncated exponential distribution family” of α spending functions proposed by Hwang et al.^[23]

$$\begin{aligned} \alpha(\gamma, t) &= \alpha \left[\frac{1 - e^{-\gamma t}}{1 - e^{-\gamma}} \right], \quad \gamma \neq 0 \quad \text{for } 0 \leq t \leq 1 \\ &= \alpha t, \gamma = 0 \end{aligned} \quad (5)$$

As noted in Hwang et al., the continuous Pocock boundary is included in Eq. 5, with $\gamma = 1$; the continuous O'Brien–Fleming boundary is also a member of Eq. 5, with approximately $\gamma = -4$ or -5 ; the “power family” member $\alpha(t) = \alpha t^{3/2}$ is closely approximated by $\gamma = -1$, and $\alpha(t) = \alpha t^2$ is approximated by $\gamma = -2$.

Group sequential methods provide a chance for early rejection of H_0 and for stopping a trial in such a way that the overall Type I error rate is maintained. The tradeoff is some loss of power, because the tests at early stages involve smaller sample sizes, and at later stages, the rejection regions are tighter (both implying lower power.) To have the same power as the fixed size design, a group sequential trial would require a larger *maximum* sample size, but the *average* sample size would still be smaller (under H_A). The maximum sample size factor is a function of the Type I and Type II errors, the number of analyses, and the way of spending α .

Some authors^[21,24] tried to search for “optimal boundaries” that minimize *average* sample size or the expected first boundary crossing time under a given H_A and power. However, in practice, the choice of boundaries is usually based more on clinical decisions and the nature of the trial than the statistical properties. For example, with either the “power family” or the “truncated exponential family,” one can choose a member (e.g., $\gamma = 0$ in Eq. 5) for a uniform spending of the Type I error. Choosing a member

(e.g., $\gamma > 0$, usually $1 \leq \gamma \leq 4$) for a concave spending of the Type I error is suitable for short-term trials with immediate response, such as single-dose analgesic studies using time-to-pain-relief as the endpoint, or when accelerated early stopping is desirable in the early phase of drug development. A negative γ in Eq. 5 (usually $-5 \leq \gamma \leq -1$, including the O'Brien–Fleming boundary) is for convex spending, which is suitable for a large mortality trial where the patient recruitment is slow and staggered and the follow-up period is long term so that very early stopping with limited samples is not much encouraged. As was pointed out by Kim and DeMets,^[21] the more convex the Type I error spending function is, the more powerful the group sequential test is.

Partial Sum Process with Independent Increments

Most of the group sequential methods were developed earlier using immediate response, either continuous or binary, where cumulative sums of the independent random variables from time to time are easily seen to have independent increments. The usefulness of this “partial sum with independent increments” property was seen in the previous section on “Type I Error Spending/Use Function Approach.”

An important development was provided by Tsiatis,^[25,26] who showed that the log-rank statistic computed over time behaves much like a partial sum of independent normal random variables. This result extended the use of group sequential methods to clinical trials with survival data. (See the entry on *Survival Analysis*.) Recently, Jennison and Turnbull^[27] provided a unified theory that explains the “independent increments” structure commonly seen in group sequential test statistics. Scharfstein et al.^[28] demonstrated that all sequentially computed Wald statistics based on efficient estimators [e.g., maximum likelihood estimators (MLEs)] of the parameter of interest will, under mild regularity conditions, have the asymptotic multivariate normal distribution similar to the earlier setup. Hence the group sequential procedure extends to more complicated situations such as the proportional hazards model^[29] and correlated observations including longitudinal data with random effects model^[30,31] or with distribution-free analyses.^[32]

Information Time/Fraction and Maximum Duration Trial Vs. Maximum Information Trial

Taking statistical information as the inverse of the variance of the parameter estimate, Lan and Zucker^[33] defined the *information time/fraction* as the amount of information accrued by calendar time divided by the total information at the scheduled end of the trial. We have seen that the information time played an essential role in the Type I error spending function approach. Depending on the statistics used (see Lan et al.^[34] for a general discussion), a complete unit information can be approximated by either a

patient (for comparing means) or an event (for comparing survival distributions). In either case, the total information must be known. If not known, as is often the case, then the information time/fraction can only be estimated.

For example, in the time-to-event case, Tsiatis^[25] showed that the variance of the log-rank statistics, when calculated over time, grows proportionally to the number of events observed. Hence the information time is equal to the proportion of the maximum number of events expected by the end of a study, with the numerator being the observed number of events at the (calendar) time of interim analysis. For a maximum information trial, the maximum number of events expected by the end of a study is chosen in advance to achieve a desired power, given other design parameters. However, for a maximum duration trial (i.e., when the maximum trial duration is fixed), the maximum information is random. In such a trial, the denominator of the information time can be estimated under either the null or the alternative hypothesis, thus leading to two information time scales.

A natural compromise to overcome this difficulty of uncertain information time scale is first to choose an estimate of the maximum information, either “under the null” or “under the alternative” hypothesis. We then set the information time to be 1 if the proportion exceeds 1 or if the current analysis is the last analysis and the proportion has not yet reached 1 (e.g., see Kim et al.^[35]). The consequence of this compromise is that the Type I error spending function will be altered from the original one that was prespecified in the design.

The following simple example^[35] illustrates the above discussion.

Example: Overrunning and underrunning.

Suppose $K = 2$ analyses were planned for a trial where the one-sided significance level of 0.05 was specified in the protocol. At the design stage, the uniform (linear) Type I error spending function $\alpha(t) = 0.05t$ was chosen for monitoring. The expected total number of events is 200 under the null hypothesis, but is 100 under the alternative. Suppose that there are 50 events at the first analysis.

If we have chosen the information time scale based on the null hypothesis, then $t_1 = 50/200 = 0.25$, and $\alpha(t_1) = 0.0125$. The group sequential boundary b_1 such that $P\{Z_{t_1} \geq b_1\} = 0.0125$ is $b_1 = 2.24$. Suppose, at the final analysis, the number of events is truly 200, as expected under the null hypothesis, the correlation between Z_{t_1} and Z_{t_2} is $(t_1/t_2)^{1/2} = (0.25)^{1/2} = 0.5$. Thus the group sequential boundary b_2 such that $P\{Z_{t_1} < 2.24, Z_{t_2} \geq b_2\} = 0.05 - 0.0125 = 0.0375$ is $b_2 = 1.74$.

However, if the realized number of events at the final analysis turns out to be 100 instead (i.e., an underrunning situation), then the “true” t_1 should be $50/100 = 0.5$ and we should have spent $\alpha(t_1) = 0.025$. But we cannot go back in time because we have already adopted $b_1 = 2.24$ for the test at the first analysis. What we can do is to recognize that 1) at $t_1 = 0.5$ (not 0.25), we used $\alpha(t_1) = 0.0125$; and 2) the

correlation between Z_{t_1} and Z_{t_2} is $(t_1/t_2)^{1/2} = (0.5)^{1/2}$. Thus the group sequential boundary b_2 such that $P\{Z_{t_1} < 2.24, Z_{t_2} \geq b_2\} = 0.05 - 0.0125 = 0.0375$ is $b_2 = 1.70$.

From the fact that $\alpha(0.5) = 0.0125 < 0.025$ (see Point 1 above), we see that the Type I error spending function was no longer the uniform (linear) spending function. Instead, it is a convex function, running under the uniform (linear) spending function.

The overrunning case is the opposite when 100 events under the alternative hypothesis was used to estimate t_1 , but it turned out that 200 events occurred at the final analysis. The consequence is that the linear spending function is altered to a concave function running over it.

Other Group Sequential Procedures: Stochastic Curtailment and Bayesian Methods

Extending the repeated significance testing procedure, a host of other group sequential procedures, frequentist or Bayesian, have been proposed in the literature. These procedures do not necessarily specify formal boundaries. They can be outlined by the following principal steps at each interim analysis: 1) divide the outcome space (the treatment–difference scale) into a region where the test treatment is considered superior and a region where the control is considered superior; and 2) guide the trial to stop if the “chance” is minimal that the control is superior (in which case we would use the test treatment), or the same is true for the test treatment (in which case we would use the control treatment). The key is that this “chance” may be measured by the conditional,^[36] posterior,^[37,38] or predictive^[39] probability of what would be the final outcome given the data at the interim stage. We then set to find the regions in step 1 by requiring certain prespecified operating characteristic. The latter two (posterior and predictive) approaches are considered preferable by Bayesian statisticians.^[40] Lin et al.^[41] advanced a general theory on stochastic curtailment for censored survival data, which provided an analytical basis of several previously proposed methods based on conditional power.

OTHER MONITORING MATTERS

Data Monitoring Committee

In order to ensure objectivity and to safeguard the blinding of the study, trials that use a group sequential design often have a DMC to evaluate the interim analyses and relevant external information. The ICH guidelines (E9, Sections 4.5 and 4.6) also call for an external Independent Data Monitoring Committee (IDMC) to be formed for monitoring comparisons of efficacy and/or safety outcomes for trials that have major public health significance. The composition of a DMC membership usually involves disciplines in the following areas: clinical,

laboratory, epidemiology, biostatistics, data management, and ethics.^[42] The organization structure for a DMC to function varies from trial to trial. For example, government-sponsored collaborative trials usually have a different reporting structure from industry-sponsored trials. More references on the DMC issues can be found in Friedman and DeMets,^[43] Fleming and DeMets,^[44] DeMets et al.,^[45] Armstrong and Furberg,^[46] and Freidlin et al.^[47]

When a DMC reviews interim data, not only the outcome measures (primary and secondary) are involved, but also the recruitment, baseline variables, adverse effects, and compliance. An early termination of a trial is a serious matter, and considerations of such cover a wide range issues of baseline comparability, quality of the data, internal and external consistency of the results, risk and benefit ratio, length of the follow-up, public impact, and, of course, the probability of Type I and Type II errors. Group sequential boundaries often serve as an important “guide-line”—not an absolute “rule”—in the consideration.

Confidence Intervals Following A Group Sequential Test

In addition to the hypothesis testing, the calculation of a confidence interval for the difference of treatment effects θ is often an important part of data analysis. A problem analogous to an inflation of the Type I error arises when estimating the population parameters upon a termination of a group sequential procedure because the study is stopped preferentially when extreme data have been observed. Thus the usual fixed sample estimators are biased toward the extremes.

The duality of hypothesis testing and confidence interval estimation, however, is helpful for the problem. Basically, the confidence interval of θ involves an inversion of the acceptance region of the test statistic, which, in turn, in the sequential testing setting, involves the boundary crossed, the stopping stage ($i = M$), and the cumulative/partial sum of the observations at the stopping stage ($S_i = S_M$). Because the acceptance region is based on “nonextreme” results for the sufficient statistic (i, S_i), clearly an ordering on the outcome space of (i, S_i) is necessary. However, the best choice for such an ordering is not as clear, as pointed out by Emerson and Fleming,^[48] because the densities for the group sequential statistics lack a monotone likelihood ratio, so the theory regarding the uniformly most powerful tests and the uniformly most accurate confidence bounds does not apply. For the binomial parameter, Jennison and Turnbull^[49] proposed a procedure based on an intuitive outcome space ordering, in which results corresponding to earlier termination are regarded as more extreme than those that terminate later. This approach was then adopted to the normal mean case by Tsiatis et al.^[50] Chang and O’Brien^[51] investigated an ordering based on the likelihood ratio test for the binomial case, then Chang^[52] applied the same approach to the normal mean case. In both cases, the

likelihood ratio ordering of the sample space was shown to give shorter confidence intervals, but Emerson and Fleming^[48] reported that there were occasions in which the confidence set based on the likelihood ratio was not an interval. Emerson and Fleming^[48] proposed the ordering based on sample mean. Confidence intervals based on the sample mean ordering agree with the test results for all practical group sequential test designs, in the sense that a $(1 - 2\alpha)$ confidence interval will not include hypotheses that are rejected by a one-sided level- α group sequential test. For random group sizes, Emerson and Fleming also recommended the approximate confidence intervals based on the sample mean ordering as well as the approximation to the bias-adjusted mean method of Whitehead.^[53]

OTHER RECENT DEVELOPMENTS

Early Acceptance/Rejection of the Null Hypothesis, Type I and Type II Error Spending Function Approaches, and Group Sequential Equivalence Trials

Group sequential methods allowing an early acceptance of the null hypothesis for futility is as important and as popular as that for an early rejection of the null hypothesis in the sense of ethics and economics. DeMets and Ware^[54,55] have proposed modifications to the Pocock and the O’Brien–Fleming designs to test one-sided hypotheses with an allowance for an early stopping in favor of the null. Gould and Pecore^[56] proposed a procedure that takes the cost function into account and pointed out that, although these procedures are less powerful than the ones that allow early rejection only, the saving of cost can be much greater. Lan and Friedman,^[57] when emphasizing the one-sided null hypothesis as being a “harmful” direction for the test treatment, suggested a combination of Type I error spending function for the upper boundary and a conditional probability (stochastic curtailment) approach for the lower boundary. An extension of the idea of the flexible Type I error spending function is naturally the use of both Type I and Type II error spending functions in constructing the rejection and acceptance boundaries.^[58,59] Recently, the idea of both acceptance and rejection boundaries has also been extended to group sequential equivalence trials by Whitehead.^[60]

Sequential Monitoring Trials with Multiple (Survival) Endpoints

In addition to the interim analyses with repeated measurements previously mentioned (“Partial Sum Process with Independent Increments”), the design of group sequential clinical trials with multiple endpoints in general or in survival outcomes has also been considered by other authors. Tang et al.^[61] addressed multivariate normal distribution

based on the global test of O'Brien.^[62] Previously generated group sequential boundaries can be used for the combined test statistic. Lin^[63] proposed a sequential non-parametric testing for detecting the stochastic ordering of two multivariate distributions, with an emphasis on multiple time-to-event endpoints, based on the weighted sum of linear rank statistics. Stopping boundaries that preserve the overall significance level and that may lead to earlier trial termination than procedures based on univariate survival endpoints were computed. Williams^[64] extended the method of Lin by developing approaches for constructing repeated joint confidence regions for the hazard ratios, in the spirit of Jennison and Turnbull,^[65,66] based on inverting linear rank statistics in terms of the parameter of interest. Technically, in all procedures, the basic building blocks are the same as that laid out earlier in "Statistical Methods," namely, finding the joint distribution (asymptotically, if necessary) of the test statistic over time by forming the test statistic at each time as a sum of i.i.d. random variables. The property of partial sum with independent increment structure can then be utilized to fit in the flexible Type I (and Type II) spending function framework. Of course, as in the nonsequential case, for the procedure to be meaningful, the endpoints being combined need to be biologically related and to demonstrate treatment effects in the same direction.

Monitoring Design Specifications to Extend a Trial

The traditional group sequential methods, as just reviewed, have been focused on an early termination of a trial for ethical and economic reasons. Recently, considerable interest has also been expressed in possibly extending a trial beyond its originally planned sample size and/or duration, based on interim data. This occurs when the assumed values for some parameters used for the initial sample size and/or duration calculation are uncertain, as is often the case for a new treatment studied for an unfamiliar disease. For example, the within-group variance may be underestimated initially, or treatment effects are less, or patient accrual rate is slower, than anticipated. Allowing for an upward adjustment of the sample size or study duration can prevent a trial from being inconclusive because of underpower after investing considerable resources.

Most of the methods in this area suggest a two-stage design because of practical logistics involved in extending a trial. Wittes and Brittain^[67] termed the first stage/phase an *internal pilot study*. Their procedure was further studied in Refs. [68,69]. For the univariate continuous case, Shih^[70] and Gould and Shih^[71] proposed two procedures to estimate the within-group variance without breaking the treatment codes and to update the sample size needed to secure the planned power of the trial. A computer program is available on the Web.^[72] Shih and Gould^[73] extended the technique to the case of repeated measures where the

key response is the slope. Shih and Long^[74] examined the robustness of the procedure with unequal variances and center effects present in the trial. For the binary case, Gould^[75] suggested using the pooled event rate, and Shih and Zhao^[76] proposed a simple design with a dummy stratification to reestimate the sample size without breaking the treatment code at the interim stage. To keep the treatment code masked is essential for maintaining the integrity of a trial where no IDMC is employed. Because these procedures only increase sample size and/or duration when necessary (otherwise they keep the original size and/or the duration intact) through updating nuisance parameters without unveiling the treatment effects at the interim stage, the Type I error probability is affected minimally, if at all. Gould and Shih^[77] and Whitehead et al.^[78] recently further examined strategies to combine blinded sample size reestimation with the traditional group sequential designs. See recent reviews in Refs. [79,80].

When an IDMC was in place and unblinding was not an issue, Andersen,^[81] Henderson et al.,^[82] Proschan and Hunsberger,^[83] Cui et al.,^[84] and Li et al.^[85] proposed the use of conditional power for updating the design specifications and extending a trial. For more complex group sequential designs (e.g., multiple arm and factorial with arbitrary survival curves), Halpern and Brown^[86] and Natarajan et al.^[87] developed simulation-based programs. Recently, Scharfstein and Tsiatis^[88] proposed to use the interim data to revise the initial guesses in the computer simulation, and to update the study design to attain the maximum information.

Abstract

Group Sequential Tests and Variance Heterogeneity in Clinical Trials In clinical trials, investigators conduct a series of interim analyses of such summary statistics as means and variances in order to decide whether to terminate the trial early. The focus of this entry, is a discussion of the variance heterogeneity problem and its impact on the Type I error of group sequential test procedures in clinical trials.

INTRODUCTION

In clinical trials, investigators conduct a series of interim analyses of such summary statistics as means and variances in order to decide whether to terminate the trial early. If a treatment is deemed beneficial to patients, it is more ethical not to wait until the trial ends to provide patients with a better treatment.^[1–4] In multiarmed trials involving g populations/treatments, investigators must not only conduct an analysis of the variances in the data but also deal with the usual multiple comparison problems associated with this process.^[5,6]

In addition, the trial can suffer from the variance heterogeneity problem.^[7] Variance heterogeneity problem can occur in any empirical investigation and it is important for practitioners to be fully aware of the consequences.^[8] When such a problem is identified in the trials, investigators have dealt with the problem by transforming the data to achieve variance homogeneity. If transforming the data is undesirable or produces unsatisfactory results, some studies have suggested the use of nonparametric tests.

In this entry, we discuss the variance heterogeneity problem and its impact on the Type I error of group sequential test procedures in clinical trials. We discuss an alternative that is based on approximation theory while using common procedures.^[7] Because group sequential procedures typically involve small samples at each interim analysis and given that most current methods do not allow for corrections for heterogeneity, the impact on the type I error of the procedure can be quite significant.^[7]

We present an application of the significance level method^[1] of group sequential procedures for such

situations. We illustrate the application by using Pocock^[2]- and O'Brien–Fleming^[3]-type group sequential boundaries to compare the means of continuous treatment outcomes. This entry is organized as follows. In Group Sequential Procedures the Pocock and O'Brien–Fleming methods and the significance level approach are defined. The section Group Sequential Procedures Under Variance Heterogeneity introduces an approximate degrees of freedom correction method for the significance level approach to account for heterogeneity. The next section extends to multiarmed trials and discusses contrasts and trend tests as well as multiple comparison problems. Concluding remarks are provided in the section on related issues.

GROUP SEQUENTIAL PROCEDURES

In a sequential clinical trial comparing two treatments, suppose a total of K interim analyses are scheduled to test the two treatment means

$$H_0 : \mu_1 = \mu_2 \quad \text{vs.} \quad H_0 : \mu_1 \neq \mu_2 \quad (1)$$

and σ_1^2, σ_2^2 are known or unknown nuisance parameters. We denote $\rho = \sigma_1/\sigma_2$. Consider responses $(x_{11}, x_{12}, \dots, x_{1n_{1k}}, \dots)$ from the distribution $N(\mu_1, \sigma_1^2)$ for treatment A, and $(x_{21}, x_{22}, \dots, x_{2n_{2k}}, \dots)$ from the distribution $N(\mu_2, \sigma_2^2)$ for treatment B. At the k th interim analysis, let $n_k = n_{1k} + n_{2k}$ be the total cumulative number of observations on both treatment arms and let the summary statistics $\bar{x}_{1k}, \bar{x}_{2k}, s_{1k}^2, s_{2k}^2, s_{pk}^2$ represent, respectively, sample means, sample variances (unbiased), and the sample pooled estimator of variance

based on the n_{1k} and n_{2k} samples available at the k th interim investigation.

In general, at the k th interim analysis, the ratio

$$T_k = \frac{\hat{\delta}_k}{SE(\hat{\delta}_k)} \quad (2)$$

is used for testing purposes, where $\hat{\delta}_k = \bar{x}_{1k} - \bar{x}_{2k}$ and $SE(\hat{\delta}_k)$ is the estimated standard error of $\hat{\delta}_k$.

A fixed-sample testing procedure corresponds to a single analysis with $K = 1$. In this case, if the variances are known, the ratio becomes the normal Z-score. Hence, we reject H_0 at level α if $|T_1|$ exceeds $z(\alpha/2)$, the upper $(100\alpha/2)$ th percentile point of the standard normal distribution. On the other hand, if we can assume $\rho = 1$ so that the two variances have common but unknown value, then we can pool the sample variances to get a robust estimator of the common population variance by using $SE(\hat{\delta}_1) = s_{p1} \sqrt{1/n_1 + 1/n_2}$ in the ratio of Eq. (2). In this case the ratio Eq. (2) has the exact t -distribution with $\nu = n_1 + n_2 - 2$ degrees of freedom. Therefore, we reject H_0 at level α if $|T_1|$ exceeds $t_{\nu}(\alpha/2)$, the upper $(100\alpha/2)$ th percentile point of a student's t -distribution with $\nu = n_1 + n_2 - 2$ degrees of freedom. This test is known to be uniformly most powerful (UMP) under the given assumption.

The original group sequential procedures of Pocock^[2] and O'Brien–Fleming^[3] were developed for the known variance case with evenly incremented group sizes (i.e., $\sigma_1^2 = \sigma_2^2 = \sigma^2$ and $n_{1k} = n_{2k} = mk$ for some constant m). To account for multiple testing, Pocock^[2] and O'Brien and Fleming^[3] suggested to reject H_0 at the k th interim analysis if the Z-score exceeds $c_k = C_p(K, \alpha)$ or $c_k = \sqrt{K/k} C_{\text{OBF}}(K, \alpha)$, respectively, where $C_p(K, \alpha)$ and $C_{\text{OBF}}(K, \alpha)$ are constants depending on α and K , obtained via numerical integrations that exploit the independent increment structure of the interim Z-scores (see also Armitage^[9]).

Furthermore, when the variances are equal but unknown, an approach originally suggested by Pocock and known as the “significance level approach” can be used.^[2] In the significance level approach, to account for estimating the denominator of Eq. (2), H_0 is rejected at level α at the k th interim analysis stage if $|T_k|$ exceeds $t_{\nu_k}(\alpha_k)$ with $SE(\hat{\delta}_k) = s_{pk} \sqrt{1/n_{1k} + 1/n_{2k}}$ where $\alpha_k = 1 - \Phi(c_k)$, c_k are the Pocock^[2] or O'Brien–Fleming^[3] critical boundaries for the known variance case, and $\Phi(\cdot)$ is the cumulative distribution function of the standard normal and $\nu_k = n_k - 2$. This approach is applicable to a variety of different types of alternative hypotheses and can also account for deviations from the condition of equally spaced group sizes as long as these deviations are not too severe.^[4]

Last, for large samples, the semiparametric efficiency theory applies.^[10] The semiparametric efficiency theory^[10] states that the ratios in Eq. (2) at consecutive interim analyses, using a nonpooled standard error estimate for $\hat{\delta}_k$, have an independent increment structure and are jointly

normal for large samples. Thus, the O'Brien–Fleming and Pocock critical values, c_k , developed for the known variance case, can still be used even with nonpooled sample variances. See also Kittelson and Emerson^[11] and Jennison and Turnbull.^[12] Therefore, a procedure based on the large sample theory would reject H_0 , if the $|T_k|$ in Eq. (2) with $SE(\hat{\delta}_k) = \sqrt{(s_{1k}^2/n_{1k}) + (s_{2k}^2/n_{2k})}$ exceeds c_k obtained by either the Pocock^[2] or O'Brien–Fleming^[3] methods.

GROUP SEQUENTIAL PROCEDURES UNDER VARIANCE HETEROGENEITY

When variance heterogeneity is present, we cannot assume $\rho = 1$, and the variance estimator cannot be pooled. Therefore, the ratio in Eq. (2) does not have an exact t -distribution. There is no UMP test whose distribution is free of the nuisance parameter ρ .^[13,14] This problem is known as the Behrens–Fisher (BF) problem. Hussein and Carriere^[7] proposed a modification of the Pocock^[2] and O'Brien–Fleming^[3]-type group sequential t -test procedures^[4] to make the procedures suitable for use under variance heterogeneity in small sample interim analyses. Although there are no serious problems when the sample size is large or the design is balanced,^[15] modification is usually needed for small sample trials. Note that $\rho = 1$ is a default assumption in the most commonly used group sequential software, PASS^[16] and S + SeqTrial.^[17]

Many investigators have considered approximate solutions to variance heterogeneity problems in comparing two sample means. The Welch^[13] approximation utilizes the fact that the distribution of the random variable $(SE(\hat{\delta}))^2 / \sigma^2$ is approximated by $e\chi_{\nu'}^2 / \nu'$. Then, by equating their first two moments, we solve for e and ν' . Welch^[13] found that $e = 1$ and

$$\nu'^{-1} = c^2(n_1 - 1)^{-1} + (1 - c)^2(n_2 - 1)^{-1} \quad (3)$$

with $c = (s_1^2/n_1) / (SE(\hat{\delta}))^2$ where n_1 and n_2 are the sizes of the two samples. Hence, the ratio in Eq. (2) will have an approximate t -distribution with ν' degrees of freedom, which depends on an estimate of ρ from the sample. This idea has been extended in various contexts and settings.^[18–23]

In group sequential trials using the significance level approach with planned K analyses, Welch's approximation can easily apply at each k interim analysis. Hussein and Carriere^[7] used the significance level approach of Pocock^[2–4] along with Welch's correction^[13] to the degrees of freedom of the two-sample t -statistic under variance heterogeneity. The procedure using the significance level approach with Welch's correction would reject H_0 at level α if $|T_k| \geq t_{\nu_k}(\alpha_k)$ with $SE(\hat{\delta}_k) = \sqrt{(s_{1k}^2/n_{1k}) + (s_{2k}^2/n_{2k})}$, and

$\alpha_k = 1 - \Phi(c_k)$. A rearrangement of Eq. (3) leads to the approximate degrees of freedom at the k th analysis as

$$\nu'_k = \frac{\left(\left(\frac{s_{1k}^2}{n_{1k}} \right) + \left(\frac{s_{2k}^2}{n_{2k}} \right) \right)^2}{\left(\frac{s_{1k}^4}{(n_{1k}^2(n_{1k}-1))} \right) + \left(\frac{s_{2k}^4}{(n_{2k}^2(n_{2k}-1))} \right)} \quad (4)$$

for $k = 1, \dots, K$. Note that for equal sample sizes and equal sample variances, it can be shown that the ν'_k reduces to $\nu_k = n_k - 2$. However, this correction generally leads to a narrower confidence interval when the variances are actually equal.^[13]

Hussein and Carriere^[7] reported the performance of their modified group sequential method using the Pocock and O'Brien–Fleming procedure in simulation, and compared the results with those of the large sample method mentioned above. Both balanced and unbalanced designs were examined to see the effect of having large variances associated with a small sample size (negative association) and large variances with a large sample size (positive association). The case of $\rho = \sigma_1^2 / \sigma_2^2 < 1$ corresponds to the design where the larger variance is associated with the larger sample, while the case of $\rho > 1$ corresponds to the design where the larger variance is associated with the smaller sample. The modified procedure was more accurate than the method based on large sample theory, regardless of how well balanced the design is and how large the degree of variance heterogeneity.

Specifically, when an investigator uses the large sample method, the empirical size deviates quite considerably from the nominal level, especially for small samples. This is true even for the case of equal variances in balanced designs. However, the inaccuracy in this case may be purely due to the use of a Z -value when the critical value from a t -distribution should have been used for small sample cases. The inflation of the empirical size becomes worse as the number of interim analyses, K , increases, and as ρ deviates from 1 for balanced cases, or as ρ increases for unbalanced cases (i.e., when small samples are associated with large variances). Especially when using Pocock's procedure, the deviation of the empirical Type I error from the nominal level is greater than those described above when $K > 1$. This remains true even for a total sample size as large as $n_K = 480$. This may be because Pocock's procedure has narrower boundaries at the early stages of analyses when the sample is small and the large sample theory is more vulnerable.

On the other hand, the empirical sizes of the Welch corrected method are in excellent agreement with the nominal level for all K and ρ , whether or not the design is balanced.^[7] For a small sample test using Welch's correction, designs with $\rho = n_{1k}/n_{2k}$ were found to be optimal, in the sense that they maximize power.^[24] The performance of the large

sample method improves as the sample size increases and is comparable to small sample tests using Welch's correction. However, the approach using Welch's correction consistently produced excellent results. The empirical size based on the modified method is virtually identical to the nominal level, even at a small total sample size of $n_K = 60$. Also, the procedure using the assumption of $\rho = 1$ should not be used as it often produces extremely conservative results. See Hussein and Carriere^[7] for details.

EXTENSION TO MULTIARMED TRIALS

An immediate extension of the two-sample comparison is to multiarmed comparison problems with more than two treatments. Suppose that the accumulating data are from parallel g groups. That is, we have x_{ij} , $i = 1, \dots, g$, $j = 1, \dots, n_i$. At the k th interim analysis there are n_{ik} cumulative observations collected on the i th arm and, hence, a total number of subjects of $n_k = \sum_{i=1}^g n_{ik}$. Furthermore, the observations of the i th arm are assumed to be normally distributed with mean μ_i and variance σ_i^2 .

In such multiarmed trials, investigators may be interested in testing the global omnibus hypothesis that the means of all arms are equal

$$H_0 : \mu_1 = \mu_2 = \dots = \mu_g \quad (5)$$

with some variance σ_i^2 . If the arms are homogenous (i.e., σ_i^2 are equal but unknown), then the usual analysis of variance principles apply and a group sequential procedure would reject H_0 at the k th interim analysis if

$$F_k = \frac{1}{(g-1)s_{pk}^2} \sum_{i=1}^g n_{ik} (\bar{x}_{ik} - \bar{x}_k)^2 \geq c_k \quad (6)$$

for any $k = 1, \dots, K$. Here, $\bar{x}_{ik}$, $\bar{x}_k$, and s_{pk}^2 are the sample mean for the i th arm, the grand sample mean for all arms and the pooled estimate of the common variance, all based on the cumulative data up to the k th interim analysis, respectively. At each k , the F_k follows an F -distribution with $(g-1)$ and $(n_k - g)$ degrees of freedom.

For equal group sizes, the monitoring boundary values, c_k , of Pocock or O'Brien–Fleming are obtained by using either the recursive integration formulae in Jennison and Turnbull^[25] or the significance level approach.^[1] In the latter case, c_k is given by $c_k = F_{g-1, (n_k-g)}^{-1}(1 - \alpha'_k)$ where $f_{\nu_1, \nu_2}^{-1}(1 - \alpha')$ denotes the $(1 - \alpha')$ -percentile point of F distribution with ν_1, ν_2 degrees of freedom, and $\alpha'_k = 1 - P(\chi_{g-1}^2 \leq c'_k)$ where c'_k are boundaries obtained for the case of common and known variance, i.e., for monitoring a χ^2 test statistic. The exact c'_k for monitoring a chi square with degrees of freedom up to 5 are tabulated in Jennison and Turnbull.^[25]

When the arms are heterogenous, the investigator can adopt the Welch approximate test (see, for example,

Welch^[26]) for the above global hypothesis. At the k th interim analysis, we reject the null hypothesis (5) if

$$F_k^w = \frac{\sum_{i=1}^g \left(\frac{\hat{w}_{ik}}{(g-1)} \right) (\bar{x}_{ik} - \bar{x}_{\cdot k})^2}{\left\{ 1 + \frac{2(g-2)}{g^2-1} \sum_{i=1}^g \frac{1}{n_{ik}-1} \left(1 - \frac{\hat{w}_{ik}}{\sum \hat{w}_{ik}} \right)^2 \right\}} \geq c_k \quad (7)$$

where $\hat{w}_{ik} = n_{ik} / s_{ik}^2$, n_{ik} is the cumulative sample in the i th treatment arm up to the k th interim analysis stage and s_{ik}^2 is the nonpooled within-arm variance estimator. The above statistic, F_k^w in Eq. (7), follows an approximate F_{ν_1, ν_2} distribution with degrees of freedom $\nu_1 = g - 1$ and

$$\nu_2 = \left\{ \frac{3}{g^2-1} \sum_{i=1}^g \frac{1}{n_{ik}-1} \left(1 - \frac{\hat{w}_{ik}}{\sum \hat{w}_{ik}} \right)^2 \right\}^{-1} \quad (8)$$

Therefore, the monitoring constants c_k can be obtained either by recursive integration or by using the significance level approach.

Example 1: Consider a trial comparing three treatments ($g = 3$). The investigator is interested in testing hypothesis (5) using the OBF-type of boundary and considers $K = 4$ interim analyses with equally spaced group sizes and overall significance level $\alpha = 0.05$. The variances of the three treatments are not assumed to be equal. Then from Jennison and Turnbull^[25] (Table 2b), we find $C_{\text{OBF}}(g-1, K, \alpha) = C_{\text{OBF}}(2, 4, 0.05) = 6.20$. Therefore, the exact monitoring boundaries for a χ^2 with two degrees of freedom are $c'_k = 6.20\sqrt{4/k}$, $k=1, 2, 3, 4$. Using Welch's statistic, we reject H_0 at the k th interim analysis if Eq. (7), based on the collected data, holds with $c_k = F_{2, \nu_2}^{-1}(1 - \alpha'_k)$, $\alpha'_k = 1 - P(\chi^2_2 \leq 6.20\sqrt{4/k})$ and ν_2 is obtained from Eq. (8) above. Note that, not only the statistic in the left-hand side of Eq. (7) but also c_k has to be computed from data, since ν_2 is a data-dependent quantity that cannot be computed ahead of time.

RELATED ISSUES

Multiple Comparisons

Once the omnibus test Eq. (5) is rejected, we are interested in performing multiple comparisons of the g arms to identify where the differences come from. A great deal of methodology has been developed for the fixed-sample case. In the context of group sequential procedures, only large sample methods have been suggested to date. Hellmich^[5] provides an excellent review for applying various multiple comparison group sequential procedures. In this entry, we

describe two approaches to the multiple testing problem that can easily utilize a combination of approximate solutions to the variance heterogeneity problem and the significance level approach. These procedures, suggested by Follmann, Proschan, and Geller^[6] are essentially pairwise comparison methods. They strongly control the family-wise Type I error rate in the sense that the probability of rejecting at least one of the true pairwise null hypotheses does not exceed the nominal α .

Suppose that all pairwise comparisons of g arms are of interest. We have $H_0^{ij} : \mu_i = \mu_j$, with $1 \leq i, j \leq g$ null hypotheses to be tested. To test each of these hypotheses, the usual t -test

$$|T_k^{ij}| = \left| \frac{\hat{\delta}_k^{ij}}{\text{SE}(\hat{\delta}_k^{ij})} \right|$$

is used at the k th interim analysis where $\hat{\delta}_k^{ij} = \bar{x}_{ik} - \bar{x}_{jk}$ is the difference between sample means for the i th and j th arm based on data collected up to the k th interim analysis stage. When the variances are heterogeneous, the standard error of $\hat{\delta}_k^{ij}$ is the nonpooled estimator, $\text{SE}(\hat{\delta}_k^{ij}) = \sqrt{(s_{ik}^2/n_{ik}) + (s_{jk}^2/n_{jk})}$, as previously described.

The first and simplest approach to controlling the family-wise type I error is to monitor each pairwise test statistic separately with the Bonferroni adjusted α . If we fix the nominal type I error to be α then the nominal for each pairwise comparison will be $Q^{\text{Bon}} = \alpha/I$ where $I = g(g-1)/2$ is the number of all possible pairwise hypotheses to be tested. Thus, each of these hypotheses is treated as an independent two-sample group sequential test, and its monitoring boundaries are obtained using the methods of Pocock, O'Brien–Fleming or others who have suggested appropriate solutions. This method is obviously very conservative and is expected to be low in power.

The second approach, as originally developed by Follmann, Proschan, and Geller^[6] is to treat the set of all test statistics for all pairwise comparisons and from all interim stages as one multivariate vector. Follmann, Proschan, and Geller^[6] showed that this vector is asymptotically multivariate normal with a certain covariance matrix. They assumed that, at each interim analysis, all pairwise hypothesis are evaluated using the same critical value (seeking equal evidence), all group variances are the same, and sample sizes are evenly distributed across arms and interim analyses. Then, under these assumptions, they obtained Pocock- and OBF-type boundaries (see also Table I of Hellmich^[5]) by simulating the jointly normal vectors.

We can adapt the above approaches to the multiple comparison problem with variance heterogeneity by using the tabled constants^[5,6] as follows: reject H_0^{ij} at the k th interim analysis if $|T_k^{ij}| \geq t_{\nu_k}(\alpha'_k)$ where $\alpha'_k = 1 - \Phi^{-1}(c_k)$ and c_k is the boundary obtained from the table in Follmann, Proschan, and Geller^[6] for the k th interim

analysis and for the appropriate number of arms g and number of interim analyses K . The degrees of freedom, ν_k^{ij} , can be set as those of Welch's correction, calculated using the formula Eq. (4) given in "Extension to Multiarmed Trials."

Using the Follmann–Proschan–Geller approach, if inferior arms are dropped during the course of the trial, one has to make sure that information fraction (i.e., the ratio of the actual number to the planned number of patients for the current arms) is not less than that at the preceding interim analysis and the information time must not decrease. In particular, this is satisfied if the total number of planned subjects is evenly distributed across arms and interim analysis. Thus, inferior arms may be dropped and the procedure may be based only on samples from the remaining arms using the original boundaries. However, this can cause the procedure to be conservative and reduce power. To alleviate this problem, Follmann, Proschan, and Geller^[6] propose a sequential rejection procedure, which strongly controls the type I error for three or less number of arms (in the case of all pairwise comparisons) and for any number of arms (in the case of comparisons to a common control). After dropping inferior arms, boundaries are recalculated based on the current number of arms and the originally planned number of interim analyses (see the following example). The Bonferroni approach is not affected because each pairwise comparison is designed separately. Note that, because of the use of the significance level approach, the above procedure allows for unequally incremented group sizes. In other words, the fraction of patients recruited between each two interim analyses need not be exactly $1/K$ of the total number of patients that the investigator plans to have for the study, although such a deviation from the planned equally spaced groups should be kept to a minimum.

Example 1: Consider all pairwise comparisons among $g = 4$ treatment arms. Suppose we plan $K = 4$ interim analyses using OBF boundaries and $\alpha = 0.05$. Thus, $I = 4(4 - 1)/2 = 6$ different pairs of treatments are to be compared. Whether using the Bonferroni adjustment method or the Follmann–Proschan–Geller method,^[6] each pair of treatments (i, j) is monitored separately and the hypothesis rejected at the k th interim analysis if its corresponding nonpooled t -test statistic $|t_k^{ij}|$ exceeds $t_{\nu_k^{ij}}(\alpha'_k)$ where $\alpha'_k = 1 - \Phi^{-1}(c_k)$. If the investigator uses the Bonferroni adjustment, then a total nominal $\alpha^{\text{Bon}} = 0.05/6 = 0.0083$ is to be used for each pairwise comparison. Therefore, $c_k = C_{\text{OBF}}(K = 4, \alpha^{\text{Bon}} = 0.0083) \sqrt{4/k} = 2.6706 \sqrt{4/k}$ for $k = 1, 2, 3, 4$. The OBF constants $C_{\text{OBF}}(K, \alpha)$ are tabulated in Jennison and Turnbull^[25] or can be calculated using software.^[16,17] On the other hand, an investigator using the Follmann–Proschan–Geller method,^[6] which is essentially Tukey's pairwise comparison method, obtains $C_{\text{OBF}}(g, K, \alpha) = C_{\text{OBF}}(4, 4, 0.05) = 2.60$ from Table 1 of Hellmich^[5] (corresponding to

$g = A = 4, R = K = 4$ and all pairwise $\alpha = 0.05$). Thus, $c_k = 2.60 \sqrt{4/k}$ for $k = 1, 2, 3, 4$. Note that the constant C_{OBF} depends on the number of arms g , the number of analyses K , and the level α .

Now we remove inferior arms while continuing to use the originally planned boundaries in the above. However, a sequential rejection approach can be used in some situations to maintain power, as the following example illustrates.

Example 2: Consider the previous example with $g = 4$ and $K = 4$ with one of them a control. Now suppose that three treatments are compared to the control so that $I = 3$ hypotheses, $H_0^{1j}; j = 2, 3, 4$, have to be tested. Using OBF-type of boundary tabulated in Hellmich,^[5] and the sequential rejection procedure,^[6] we have $C_{\text{OBF}}(4, 4, 0.05) = 2.40$. Hence, we reject H_0^{1j} at the k th interim analysis if $|T_k^{1j}| \geq \nu_k^{1j}(\alpha'_k)$ where $\alpha'_k = 1 - \Phi^{-1}(c_k)$, $c_k = 2.40 \sqrt{4/k}$, $k = 1, 2, 3, 4$ and ν_k^{1j} are the Welch's degrees of freedom calculated from data at the k th interim analysis. For example, if arm 2 is deemed inferior and dropped at the first interim analysis ($k = 1$), we obtain $C_{\text{OBF}}(3, 4, 0.05) = 2.26$ and the monitoring boundaries $c_k = 2.26 \sqrt{4/k}$ at subsequent stages $k = 2, 3, 4$ for $g = 3$ arms and $K = 4$ interim analyses.

Contrasts and Trend Tests

Assuming that one of the global hypotheses of interest is $H_0: \sum_{i=1}^g a_i \mu_i = \mu_0$ where a_i and μ_0 are known constants with $\sum_i a_i = 0$, the test statistic at the k th interim analysis is

$$T_k = \frac{\sum_{i=1}^g a_i \bar{x}_{ik} - \mu_0}{\sqrt{\sum_{i=1}^g a_i^2 s_{ik}^2 / n_{ik}}}$$

In a fixed sample design, if the variances are homogeneous, this statistic based on a pooled sample variance follows a t -distribution with $n - g$ degrees of freedom. The trend tests that are often used in pharmacology studies fall into this category of linear hypothesis, with $a_i = i - \sum_{i=1}^g i / g$ and $\mu_0 = 0$.

In the heterogeneous case, the investigator can use Welch's generalization of the two-sample heterogeneous problem to the multisample linear hypothesis.^[27,28] When adopting this correction, one rejects H_0 at the k th interim analysis if $|T_k| \geq t_{\nu_k}(\alpha_k)$ where $\alpha_k = 1 - \Phi(c_k)$, c_k is the boundary value for the equal and known variance case and the degrees of freedom for the t -distribution are derived from Welch^[13] and are given by

$$\nu_k = \frac{\left[\sum_i a_i^2 s_{ik}^2 \right]^2}{\sum_i a_i^2 s_{ik}^4 / (n_{ik} - 1)} \quad (9)$$

Example 1: If an investigator has three treatment arms with unknown variances and wishes to test whether the means exhibit a linear trend, he or she can choose the contrast $(a_1, a_2, a_3) = (-1, 0, 1)$ so that $H_0: -1 \times \mu_1 + 0 \times \mu_2 + 1 \times \mu_3 = 0$ vs. $H_a: -1 \times \mu_1 + 0 \times \mu_2 + 1 \times \mu_3 \neq 0$. Suppose we plan four interim analyses and equally incremented sample sizes at each interim analysis (for example, at each k , $\sum_{i=1}^3 n_{ik} = 3mk$ for some constant m), a nominal $\alpha = 0.05$, and OBF monitoring boundaries. For this setup if the variances are equal and known, the upper four critical points for the OBF boundary are $c_k = C_{\text{OBF}}(K, \alpha) \times \sqrt{k/K} = C_{\text{OBF}}(4, 0.05) \sqrt{k/4}$ where the C_{OBF} is read from a table.^[1] Thus, the four positive boundary points are $c_k = 2.024 \sqrt{k/4}$ for $k = 1, 2, 3, 4$. Now, since the variances are possibly heterogenous, we reject H_0 at the k th interim analysis if

$$|T_k| = \left| \frac{\sum_{i=1}^3 a_i \bar{x}_{ik}}{\sum_{i=1}^3 a_i^2 s_{ik}^2 / n_{ik}} \right| \geq t_{\nu_k}(\alpha'_k)$$

where $\alpha'_k = 1 - \Phi(c_k)$ using the c_k found above. The degrees of freedom ν_k are calculated using Eq. (9).

CONCLUSIONS

This entry deals with clinical trials where sequential testing procedures are applied to compare summary statistics in several interim investigations. Most such clinical trials currently use the large sample method to test parameters of interest, and consequently do not produce valid study results unless the sample size is large. In fact, the available sample sizes are often very small.

We have focused on small sample problems in group sequential procedures, which can be accompanied by the variance heterogeneity problem. We have discussed Welch's corrected degrees of freedom method in the significance level approach^[4] of Pocock and O'Brien–Fleming-type group sequential methods for sequentially testing the equality of the means of two normally distributed populations. This modification produced excellent results in most cases, as the modification kept the Type I error rate at a nominal level, even for small samples. Various investigators have also reported that Welch's approximate degrees of freedom method is robust against mild departures from the normality assumption.^[8,18–23]

Even at a relatively large total sample size of $n_K = 480$, the large sample method is not entirely satisfactory, especially when using Pocock's procedure with large K . Therefore, it is important to consider modifying the significance level approach, for example, by using the method suggested by Welch. In this entry, we also discussed extensions to multiarmed trials and some linear hypothesis tests.

Human Drug Abuse Trials

Qianyu Dang

CDER, U.S. Food and Drug Administration, Silver Spring, Maryland, U.S.A.

Abstract

Human drug abuse study is an important part of evaluating a drug's effect on the human central nervous system (CNS) to produce subjective responses related to abuse potential. There are three types of pharmacodynamics (PD) clinical studies—the human abuse potential (HAP) study, the human abuse study for abuse-deterrent opioids, and the human drug withdrawal study. All of them play vital roles in a nation's effort to curb illegal use of prescription opioid drugs and other controlled substances.

Keywords: Prescription opioids; Crossover study; Abuse potential studies; Visual analogue scales.

INTRODUCTION

Human drug abuse study is an important part of evaluating a drug's effect on the human central nervous system (CNS) to produce subjective responses related to abuse potential. There are three types of pharmacodynamics (PD) clinical studies—the human abuse potential (HAP) study, the human abuse study for abuse-deterrent opioids, and the human drug withdrawal study. In April, 2015, the U.S. Food and Drug Administration (FDA) published the guidance on “Abuse-Deterrent Opioids—Evaluation and Labeling.”^[1] FDA issued the industry guidance of “Assessment of Abuse Potential of Drugs”^[2] in January, 2017. As of March 2017, there is no FDA guidance for human drug withdraw study.

HUMAN ABUSE STUDY FOR ABUSE-DETERRENT OPIOIDS

Prescription opioid drugs such as oxycodone, hydrocodone, and oxymorphone are primarily used for pain management. However, abuse of these drugs for recreational purpose has become a serious public health crisis in the United States. An important effort to curb opioid drug abuse is to develop relatively safer opioid analgesics that are formulated to deter abuse while still provide pain management for patients. Numerous new technologies have been developed to create new opioid drug formulations to deter abuse. The abuse-deterrence effect needs to be fully evaluated before the product is approved by the regulatory authority with such claims. The premarket evaluations can be divided into three categories:

1. Laboratory-based in vitro manipulation and extraction studies (category 1)

2. Pharmacokinetic studies (category 2)
3. Clinical abuse potential studies (category 3)

The human abuse study is part of category 3 studies. The need and design of category 3 studies may depend on the results of category 1 and category 2 studies.

A human abuse study for abuse-deterrent opioid drugs is typically a randomized, double-blind, placebo-controlled, and positive-controlled crossover study.^[3] Study participants are usually experienced recreational drug users familiar with the opioid drug effects. The study is composed of a prequalification phase to screen participants and assessment phase in which only qualified subjects can participate. The route of administration (intranasal, oral, or intravenous), dose selection, manipulation mode, and sample preparation for the study should be carefully chosen based on factors including epidemiological data of abuse history as well as category 1 and category 2 study findings.

In both phases, the primary tools to assess the subjective drug effects are standardized instruments include visual analogue scales (VAS) and Profile of Mood States. VAS scores are used to measure drug liking, drug high, drug-taking again, overall drug liking, good effects, and bad effects. The measure can be unipolar (0–100, with 0 to be neutral) or bipolar (0–100, with 50 to be neutral) scale. Bipolar scale is recommended in 2015 FDA guidance for primary measure of drug-liking. Drug-liking is also the primary end point of interest in most drug abuse studies.

The purpose of prequalification phase is to ensure selected subjects can differentiate between placebo and an original immediate-release formulation of the same opioid being tested in an abuse-deterrent formulation in the next phase. Subjects qualified in the prespecified acceptable range of both placebo and positive control drugs will be selected to participate in the assessment phase.

The assessment phase usually has multiple doses of positive control, test drug, and placebo. It could also include different ways of manipulation of opioid drugs such as crushing and chewing. The study is validated through comparison of positive control (C) and placebo (P) while the efficacy of abuse-deterrent effect is proven through the comparison between the abuse-deterrent test drug (T) and the positive control without abuse-deterrent properties. The primary analysis is testing the differences of means for the $E_{\max}$ of primary measures. $E_{\max}$ is defined as the maximum of responses measured in the predefined time frame after drug dosing. The purpose is to prove that T has less abuse potential than C; so it is an efficacy study. The analysis population is usually the subjects who complete all treatments and have responses of primary measures within the prespecified time interval before and after drug $T_{\max}$. Descriptive statistics include tables and graphs displaying the outcomes of interest for each treatment group as well as the differences among them.^[4]

The primary statistical analysis of drug abuse studies for abuse-deterrent opioids includes the test of the following hypotheses with regard to primary outcomes such as drug-liking, drug-high, drug-taking again, etc.:^[5]

1. *The test for deterrent effect:* Comparing the means of C and T:

$$H_0 : \mu_c - \mu_T \leq \delta_1 \text{ versus } H_1 : \mu_c - \mu_T > \delta_1 \quad (1)$$

where the test margin of $\delta_1 = \delta^* \times (\mu_c - 50)$, $0 < \delta^* < 1$. In other words, the test margin has to be greater than 0.

2. *The validation test:* Comparing the means of C and P:

$$H_0 : \mu_c - \mu_p \leq \delta_2 \text{ versus } H_1 : \mu_c - \mu_p > \delta_2 \quad (2)$$

where the test margin of $\delta_2 \geq 15$.

Both tests are two sided with the significance level to be 2.5%. All the test margins need to be predefined. The choice of δ^* is critical and should be predetermined based on preclinical and other information of the innovative formulation's abuse deterrent-effect. A closed testing procedure should be applied by starting with a prespecified and clinically meaningful δ^* . If the result of hypothesis test 1 is statistically significant, then test the hypothesis again with a 0.05 increment of δ^* until an insignificant result is achieved.

Statistical methods such as mixed models can be used to implement the hypothesis testing described above. Models should include variables that may affect how the product is used and also other related confounders (e.g., geographic variability and demographic characteristics) as fixed effects. If the model assumptions are not met, then paired t-test approaches may be considered before applying non-parametric test of median differences.

The secondary statistical analysis is based on the percentage reduction of drug-liking for test formulation T from C relative to P. For each subject, the percentage reduction is defined as:

$$\% \text{reduction} = \frac{c_i - t_i}{c_i - p_i} \times 100\%, i = 1, 2, \dots, n \quad (3)$$

Here c_i , t_i , and p_i are the $E_{\max}$ drug-liking bipolar VAS score for subject I in three treatment arms, respectively. In the situation of large Placebo response of p_i , the following definition should be applied instead:

$$\% \text{reduction} = \frac{c_i - t_i}{c_i - 50} \times 100\%, i = 1, 2, \dots, n \quad (4)$$

In case $c_i \leq 50$, the reduction will be assigned as 0.

There are two types of statistical tests for percentage reduction of abuse potential, responder analysis, and median percentage reduction. Either one can be used to support the results from primary analysis. A responder is a participant who had a minimum $\delta^* 100\%$ of reduction in primary outcomes as defined above. For example, the hypothesis test of half of the participants who are responders with at least 10% reduction is:

$$H_0 : p^* \leq 50\% \text{ versus } H_1 : p^* > 50\% \quad (5)$$

Where p^* is the percentage of responders with 10% or more reduction.

The other approach is testing the median of percentage reduction (ptr) among all subjects in the analysis data set. For example, the hypothesis test for median percentage reduction to be at least 10% is:

$$H_0 : \text{median(ptr)} \leq 10\% \text{ versus } H_1 : \text{median(ptr)} > 10\% \quad (6)$$

The Wilcoxon-signed rank test can be applied if the percentage reduction distribution is symmetrical. Otherwise, the sign test can be used. All tests and their test parameters need to be prespecified and tested at 2.5% significance level.

HAP STUDY

Under the Controlled Substances Act [CSA; (21 U.S.C. 811(b), 811(c), 812(c))], any new drug product with the potential to be abused need to be assessed for HAP. The results can be used to propose drug scheduling. The results of human drug abuse potential studies, combined with other preclinical and clinical evaluations, are used for the determination of drug scheduling by The Drug Enforcement Administration.

The design of HAP study is very similar to abuse study for abuse-deterrent opioids. Typically it includes a prequalification phase and a treatment phase. Study participants are also experienced recreational drug users. The prequalification phase includes C and P. The same C drug will be used in the treatment phase. Only subjects with acceptable responses for both P and C drugs will be eligible for the treatment phase. The treatment phase usually has multiple doses of test drug, C drug and P arms. It is commonly designed as a randomized, double-blind, double-dummy, placebo- and active-controlled, crossover study. A balanced William square design is also recommended. The primary outcomes of HAP study may include the VAS score at $E_{\max}$ of drug-liking (at the moment), drug-high, as well as overall drug-liking and drug-taking again at 12 and 24 hrs after dosing. Other subjective measures, safety and physiological measures, and abuse-related adverse events will be used to determine whether the study shows any signal of abuse. Bipolar VAS is also recommended for the primary measurement of drug-liking.

The analysis population are also subjects as defined in the abuse-deterrent study. The statistical analysis begins with descriptive statistics making up tabulations and graphs to show the responses of interest for each treatment and for each paired difference among treatments. Since it is basically a safety study, the null hypothesis should be that the test drug has abuse potential and the alternative hypothesis should be that the test drug has no abuse potential. Following hypotheses need to be tested:

1. *The validation test: C has less abuse potential than P:*

$$H_0 : \mu_c - \mu_p \leq \delta_1 \text{ versus } H_a : \mu_c - \mu_p > \delta_1 \quad (7)$$

where $\delta_1 > 0$.

2. *Test drug has greater or equal abuse potential than C:*

$$H_0 : \mu_c - \mu_T \leq \delta_2 \text{ versus } H_a : \mu_c - \mu_T > \delta_2 \quad (8)$$

where $\delta_2 \geq 0$.

3. *Test drug has greater abuse potential than P:*

$$H_0 : \mu_T - \mu_p \geq \delta_3 \text{ versus } H_a : \mu_T - \mu_p < \delta_3 \quad (9)$$

where $\delta_3 > 0$.

The actual values of δ_1 , δ_2 , and δ_3 depend on abuse potential measures, the route of drug administration, and the type of C drug, respectively. All the margins need to be prespecified.

Since most studies are crossover with repeated measures from the same subject under different treatment arms, statistical models such as mixed model can be used in analysis. If the model assumptions are not met, then paired t-test or non-parametric approaches may be considered depending on the actual data distribution. HAP is a safety study and statistical significance of the test must be achieved on all doses; no multiplicity adjustment is required.

CONCLUSIONS

Drug abuse potential refers to a medical drug that produces positive psychoactive effects, which could lead to its intentional non-medical use. Human drug abuse study is a vital part of the systematic evaluation of drug abuse potential that includes chemical, animal, human PK, human PD, and post-marketing epidemiological studies. It is also an important tool to evaluate the true effect of a new formulation of opioid pain killers developed to deter non-medical uses. This area is under extensive scientific research as we understand more about the science of these drug products.

ACKNOWLEDGMENTS

I would like to express my gratitude to FDA controlled substance statistical review team members Ling Chen, Wei Liu, and Anna Sun for their contribution to the field of human drug abuse studies through their research and review work.

Hypothesis Testing

Devan V. Mehrotra and Ivan S. F. Chan

Merck Research Laboratories, West Point, Pennsylvania, U.S.A.

Abstract

The goal of hypothesis testing is to make a data-based decision concerning the a priori hypothesized value(s), or range of values, of the parameter(s). This entry details several methods of hypothesis testing.

INTRODUCTION

A common objective of any scientific experiment is to make valid inferences about a parameter (or parameters) of a well-defined target population, on the basis of a sample of observed values from the population. For example, consider a randomized clinical trial designed to compare the effectiveness of two antihypertensive drugs, designated test (T) and control (C), in lowering systolic blood pressure after 12 weeks of treatment. For such a trial, the parameter of interest is usually $\theta = \mu_T - \mu_C$, where μ_i denotes the population mean response for drug i . In other words, μ_i is the (hypothetical) mean reduction in systolic blood pressure that would be observed if the entire target population (defined by the inclusion and exclusion criteria for the trial) could be evaluated after 12 weeks of treatment with drug i . In this example, “compare the effectiveness” could mean that the researcher is interested in estimating $\theta = \mu_T - \mu_C$ and/or seeking to demonstrate beyond a reasonable doubt that $\theta > 0$, i.e., the test drug is more effective than the control drug, on average.

In general, two separate but implicitly related approaches are commonly used to make statements about population parameters: estimation and *hypothesis testing*. In the former, an attempt is made to estimate the population parameter(s) of interest with high precision. In the latter, which is the focus here, the purpose is to make a data-based decision concerning the a priori hypothesized value(s), or range of values, of the parameter(s). Hypothesis testing permeates all branches of statistical science, and is one of the most widely used tools in scientific research. For a captivating historical development of this topic, including delightful vignettes about pioneers of hypothesis testing such as Karl Pearson, Ronald Fisher, Jerzy Neyman, and Egon Pearson, see Salsburg.^[1]

NEYMAN–PEARSON FORMULATION OF HYPOTHESIS TESTING

There are four basic elements of a hypothesis test: the null hypothesis (H_0), the alternative hypothesis (H_a), the test

statistic (T), and the rejection region of the test. In practice, H_a is often referred to as the research hypothesis, while H_0 is the “straw man” that the researcher wishes to reject by presenting evidence (sample data) against it. In our clinical trial example, we would commonly test $H_0: \theta = 0$ vs. $H_a: \theta > 0$. The test statistic, a function of the observed data, is used to choose between H_0 and H_a . The rejection region is a (possibly discontinuous) range of values of T that would be rarely observed under H_0 . Accordingly, in the classic Neyman–Pearson^[2] formulation of hypothesis testing, if the observed value of T falls in the rejection region of the test, then H_0 is rejected; otherwise, it is accepted.

Two types of error are possible in this decision process. A type I error is one in which a true H_0 is incorrectly rejected, while a type II error results from failing to reject H_0 when it is false. The probabilities of making type I and type II errors are labeled α and β , respectively, and the maximum value of α is called the size of the rejection region or, more commonly, the test size. In order to determine these error probabilities, we must first determine, either exactly or approximately, what the probability distribution of the test statistic would be if H_0 was true, the so-called null distribution of T . In general, it is important to control the test size at a low level, such as 2.5% or 5%. The power of the test, $1 - \beta$, is the probability of rejecting H_0 when it is false. For a given α , the rejection region of the test should be chosen so as to minimize the probability of a type II error, i.e., to maximize power. If there exists a particular test (defined by the test statistic and the rejection region) with greater power than any other test of the same size, the corresponding test is called a *most powerful* test. It should be noted that the concept of a most powerful test only applies when we are dealing with *simple* null and alternative hypotheses. For instance, in our clinical trial example, this could mean testing $H_0: \theta = 0$ versus, $H_a: \theta = 2$. If the alternative hypothesis is not simple, but *composite*, such as $H_a: \theta > 0$, then the chosen test is called *uniformly most powerful* if it is most powerful over the entire range of the parameter value(s) defined by the alternative hypothesis. Note that for composite hypotheses such as $H_a: \theta > 0$, the power will be

a function of θ , with power increasing as θ becomes more positive. In general, the “farther” H_a is from H_0 , the greater will be the power of the test. The power to reject H_0 can be increased by gathering more evidence (increasing sample size), and by restricting the range of potential values of the parameter(s) of interest under H_a . To clarify the latter point, suppose that the control treatment in our clinical trial example is a placebo, and that three increasing doses of the test treatment ($T_1 < T_2 < T_3$) are being studied. In addition, suppose we can assume a priori that if the test treatment is better than placebo, then a higher dose will be at least as effective as a lower dose, in the T_1 – T_3 range. The null hypothesis would be $H_0: \mu_C = \mu_{T_1} = \mu_{T_2} = \mu_{T_3}$, and a possible alternative is $H_a: \mu_i > \mu_C$ for at least one $i \in \{T_1, T_2, T_3\}$. However, this alternative does not reflect our a priori assumption of a monotonically nondecreasing treatment effect with increasing dose. Our point of clarification is that power could be increased in this situation by using a test statistic that is sensitive to detecting a restricted (and more meaningful) alternative hypothesis, namely $H_a: \mu_C \leq \mu_{T_1} \leq \mu_{T_2} \leq \mu_{T_3}$ with at least one strict inequality.

FISHER’S P -VALUE AND SIGNIFICANCE TESTING

Despite the popularity of the Neyman–Pearson formulation of hypothesis testing, it has been criticized since its inception on various grounds by several leading statisticians, including Ronald Fisher and David Cox. Recall that in the Neyman–Pearson formulation, H_0 is *accepted* if the test statistic does not fall in the rejection region. Fisher^[3–5] argued repeatedly that hypothesis tests are cogent for the *rejection* of hypotheses, but by no means for their *acceptance*. He promoted the use of P -values to quantify the magnitude of evidence *against* (not *for*) the null hypothesis. The P -value is the probability that the value of the test statistic would be at least as extreme as that observed if H_0 were true. For instance, in our clinical trial example, assuming that larger values of the test statistic would provide stronger evidence against H_0 , the P -value would be calculated as $P = P_{H_0}(T \geq T_{\text{obs}})$, where T_{obs} is the observed value of the test statistic for the data at hand.

If the null distribution of T is continuous (e.g., standard normal), then the P -value has a uniform (0,1) distribution under H_0 . Hence if we prespecify a number x , $0 \leq x \leq 1$, and reject H_0 if and only if $P \leq x$, then in the long run we will incorrectly reject H_0 with relative frequency x . Accordingly, in the Neyman–Pearson formulation of hypothesis testing, with α being viewed as the long-run probability of making a type I error, H_0 is rejected if $P \leq \alpha$, and accepted otherwise. Unfortunately, there are some problems with this commonly used decision process. For instance, when $\alpha = 0.05$, $P = 0.0499$ and

$P = 0.0501$ would lead to different decisions, which is rather unappealing. Moreover, $P = 0.0001$ and $P = 0.0499$ would be accorded the same interpretation under the Neyman–Pearson framework.

Cox,^[6] in agreement with Fisher, objected to the rigidity of the Neyman–Pearson decision process. He proposed that the P -value serve as a descriptive tool in a broader “significance testing” analysis, rather than as a decision maker to accept or reject H_0 . He cautioned that the interpretation of the P -value should take into account, among other aspects, the design of the experiment (including sample size), as well as the precision and magnitude of the estimated parameter(s) of interest. In Cox’s view, for example, a P -value of 0.045 in a smaller experiment could be deemed more “significant” than the same P -value in a larger experiment, all else being equal. See Cox^[6] for “hypothesis dividing” and “hypothesis refining” applications of P -values.

HYPOTHESES IN SUPERIORITY, NONINFERIORITY, AND EQUIVALENCE TRIALS

Returning to our clinical trial example, if it was a *superiority* trial, the purpose would be to demonstrate that the test drug is more effective than the control drug, on average. The null and alternative hypotheses would be $H_0: \mu_T - \mu_C \leq 0$ and $H_a: \mu_T - \mu_C > 0$, respectively. If it was a *superiority* trial, the purpose would be to demonstrate that the test drug is more effective than the control drug by at least a clinically significant amount Δ , on average. The null and alternative hypotheses would be $H_0: \mu_T - \mu_C \leq \Delta$ and $H_a: \mu_T - \mu_C > \Delta$, respectively. If it was a *noninferiority* trial, the purpose would be to demonstrate that the test drug is either more effective than the control drug, or less effective by at most Δ , on average. The null and alternative hypotheses would be $H_0: \mu_T - \mu_C \leq -\Delta$ and $H_a: \mu_T - \mu_C > -\Delta$, respectively.

Noninferiority trials are commonly undertaken in situations where the test and control drugs are expected to be approximately equally effective, but the former may be preferable because of reasons such as a better tolerability/safety profile, or a more convenient dosing schedule. The choice of the noninferiority bound Δ is a challenging issue in practice, and must be resolved prior to the start of the trial. In general, the choice of Δ should be based on statistical reasoning as well as clinical and regulatory judgments. More general discussions on the choice of the noninferiority bound can be found in Temple,^[7] Jones et al.,^[8] Ebbutt and Frith,^[9] Röhmle,^[10] and the ICH E10 Guideline.^[11] Both superiority and noninferiority hypotheses are implicitly associated with one-sided tests. Interestingly, however, researchers often report two-sided P -values. This can be confusing in the absence of an accompanying point or interval estimate of the parameter

of interest (here, $\theta = \mu_T - \mu_C$), because the direction of the treatment effect is masked by a two-sided P -value.

Equivalence trials are ubiquitous in pharmacokinetic applications. For example, in a typical average bioequivalence trial, the objective is to show that the test and control drugs (often two formulations of the same drug) have “equivalent” pharmacokinetic profiles, as judged by the area under the plasma-concentration time curve (AUC). The parameter of interest is usually $\theta = \mu_T/\mu_C$, where μ_i denotes the true geometric mean AUC for drug i , and we test $H_0: \theta \leq \theta_l$ or $\theta \geq \theta_u$ vs. $H_a: \theta_l < \theta < \theta_u$. As in a noninferiority trial, the equivalence bounds θ_l and θ_u must be prespecified before the trial. In practice, these limits are dictated by regulatory agencies such as the Food and Drug Administration (FDA), with common values being $\theta_l = 0.80$ and $\theta_u = \theta_l^{-1} = 1.25$. Equivalence trials inherently involve two-sided hypotheses. Interestingly, however, they are commonly analyzed using a two one-sided testing approach (TOST) in which the P -value, to support a conclusion of equivalence, is the larger of the P -values from each of the two one-sided tests (Schuirmann^[12]). The validity of this testing approach has been documented by Berger,^[13] and TOST is currently the recommended approach in regulatory submissions (ICH E9 Guideline^[14]).

BAYESIAN HYPOTHESIS TESTING

In practice, problems arise if the P -value is used to infer something about the veracity or believability of the null. For instance, some researchers incorrectly use the P -value as representing the probability that the null hypothesis is true, and this can lead to interesting paradoxes (Lindley,^[15] Shafer^[16]). Another criticism of the P -value is that it is not very useful when the sample sizes are very large. The reason is that because the null is rarely *exactly* true, increasing the sample size will eventually lead to a small P -value, and hence a rejection of the null hypothesis.

The Bayesian approach to hypothesis testing is a well-established alternative to the classic (frequentist) P -value-based inference, albeit at the “cost” of requiring a prior distribution for the hypothesized parameter(s). In the Bayesian framework, the P -value is replaced with the posterior probability that H_0 is true. If π_0 denotes the prior probability favoring H_0 , then the posterior probability that H_0 is true can be calculated as $[1 + B^{-1}(1 - \pi_0)\pi_0^{-1}]^{-1}$, where B is the “Bayes factor.” Note that B is the ratio of the posterior odds of H_0 to its prior odds. A value of $B = 1/10$ means that H_a is supported 10 times as much by the data as is H_0 . For many years, the acceptability of Bayesian hypothesis testing was limited due (in part) to lack of computational convenience in calculating B . However, recent advancements in computing and development of efficient numerical algorithms have removed that hurdle; see Berger^[17] for details on available Bayesian software. Insightful discussions on

Bayesian hypothesis testing can be found in several articles, including Berger and Delampady,^[18] Casella and Berger,^[19] Kass and Raftery,^[20] and Berger et al.^[21]

CONCLUSION

In summary, we have described the four basic elements of a hypothesis test, discussed type I and type II errors, reviewed the concepts of test size, power, and P -values, and briefly contrasted frequentist with Bayesian hypothesis testing. In any research endeavor, it is important that the postulated null and alternative hypotheses accurately reflect the intended goal of the investigation. Providing a correct statistical answer to the wrong question is often referred to as type III error, and should be avoided at all costs. Readers interested in gaining more in depth knowledge about hypothesis testing are referred to Lehmann.^[22]

Imputation with Item Nonrespondents

Hansheng Wang

Peking University, Beijing, People's Republic of China

Shein-Chung Chow

Duke University School of Medicine, Durham, North Carolina, U.S.A.

Abstract

Missing values in studies are commonly encountered. An item nonrespondent refers to a subject who fails to answer some (not all) of the items. This entry is focused on the approaches clinical researchers can take in dealing with item nonrespondents, looking closely at statistical properties.

INTRODUCTION

In clinical research, an instrument (or questionnaire) consisting of a number of items (or questions) is usually used to quantitate a subject's behavior and the ability to function in day-to-day activities as perceived by the subject. For example, the EORTC QLQ-C30 questionnaire is commonly used as a reliable instrument to measure the quality of life of patients with cancer. On the other hand, the positive and negative syndrome scale (PANSS) is useful for assessing positive symptoms (e.g., delusions, hallucinatory behavior, and hostility), negative symptoms (e.g., emotional/passive social withdrawal and poverty of thought and spontaneous activity), and general psychopathology (e.g., anxiety and depression) in schizophrenic patients and patients with schizoaffective disorder. For each item, the patient (if self-administered) or the investigator is asked to provide a rating score from 0 (none) to k (severe). A self-administered instrument is often used because it can reflect how a patient feels and may have less bias because patients feel that their answers are more confidential. However, a self-administered instrument is expected to have a larger variability due to the unstable condition of the patient. Based on patient ratings, several statistical methods for assessment of drug effects have been proposed (see, e.g., Refs. [1–3]).

OVERVIEW

In practice, missing values are commonly encountered, which can be classified into two categories, namely, unit nonrespondent and item nonrespondent (see, e.g., Wang^[4,5]). A unit nonrespondent refers to a subject who fails to answer all of the items (questions). An item nonrespondent refers to a subject who fails to answer some

(not all) of the items. In practice, because unit, nonrespondents do not provide any information regarding the treatment effect, they are usually excluded from the analysis under the assumption of missing completely at random. On the other hand, because item nonrespondents do provide partial information, it is not acceptable to exclude these subjects from analysis.

In clinical research, two approaches are commonly suggested for handling item nonrespondents. The first approach is to simply ignore all the item nonrespondents from the analysis. Although this method is statistically valid under the assumption of “missing completely at random,” it suffers from decreasing power/efficiency and from excluding too many evaluable patients from the analysis. The second approach is to impute the missing item and then calculate the total score based on the imputed data. As indicated in Shao and Wang,^[6] imputation methods in clinical research commonly include last observation carry forward (LOCF) or endpoint analysis, mean/median imputation, regression with covariates, etc. To examine the statistical properties of imputation with item nonrespondents, for illustration purpose, we will focus only on mean imputation method.

In the next section, the mean imputation approach will be described under a commonly employed statistical model. Also included in this section are the statistical properties of the estimators derived from the model based on the imputed data, in the section “Statistical inference,” two procedures including the so-called linearization procedure and the jackknife method proposed by Rao and Shao^[7] for estimation of the asymptotic variance of the derived estimators are discussed. Also included are statistical tests based on the mean imputation approach. The section “An Example” gives an example concerning the study of agitated behavior in schizophrenic patients to illustrate the use of the mean imputation method. A brief concluding remark is given in the last section.

STATISTICAL MODEL

Single-Imputation Class

In clinical research, the treatment groups are usually considered as imputation classes. The imputation will be carried out within each imputation class. For simplicity, we first consider the case of a single-imputation class. The results can be generalized to multiple-imputation classes as discussed at the end of this section.

Let $x_{ij} \in S_j$, $i = 1, \dots, n$; $j = 1, \dots, m$ be the score of the j th item from the i th subject. S_j is the finite sample space for x_{ij} . Note that S_j need not to be the same for different j . The observations from the same subject (e.g., $x_{i1}, \dots, x_{im}$) are usually correlated. However, the vectors $(x_{i1}, \dots, x_{im})'_{i=1, \dots, n}$ are assumed to be independent and identically distributed (i.i.d.) for different i . The total score of the i th subject is defined to be

$$z_i = \sum_{j=1}^m x_{ij}$$

The parameter of interest is $\mu = E(z_i) = \sum_j \mu_j$, where $\mu_j = E(x_{ij})$. Because there are missing scores, denote y_{ij} by missing scores of x_{ij} . That is, $y_{ij} = 0$ means missing and $y_{ij} = 1$ indicates not missing. As a result, $(y_{i1}, \dots, y_{im})'_{i=1, \dots, n}$ are usually correlated for a fixed i but are i.i.d. random vectors for different i . It is assumed that $E(y_{ij}) = p_j$.

For any given j , the observed sample mean for the j th item is given by

$$\bar{x}_{-j}^* = \frac{\sum_{i=1}^n x_{ij} y_{ij}}{\sum_{i=1}^n y_{ij}}$$

As a result, if x_{ij} is missing (i.e., $y_{ij} = 0$), it is replaced by x_{-j}^* . Let x_{ij}^* be the value of the j th item of the i th subject after imputation. It can be verified that

$$x_{ij}^* = y_{ij} x_{ij} + (1 - y_{ij}) x_{-j}^*$$

Hence, the total score of the i th subject after imputation is given by

$$z_i^* = \sum_{j=1}^m x_{ij}^* = \sum_{j=1}^m (y_{ij} x_{ij} + (1 - y_{ij}) x_{-j}^*)$$

It is common practice to treat the imputed values as the observed values and to obtain estimators designed based on complete data sets for estimation of the parameter of interest. In the situation where there are no missing values, the sample mean of z_i is a natural estimator for μ . Consequently,

the sample mean of z_i^* becomes our estimator for μ , which is given by

$$\begin{aligned} \hat{\mu}^I &= \frac{1}{N} \sum_{i=1}^n z_i^* = \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^m (y_{ij} x_{ij} + (1 - y_{ij}) x_{-j}^*) \\ &= \sum_{j=1}^m \left(\frac{\frac{1}{n} \sum_{i=1}^n x_{ij} y_{ij}}{\frac{1}{n} \sum_{i=1}^n y_{ij}} \right) \end{aligned}$$

The following theorem can be obtained.

Theorem 1. Assuming single-imputation class, based on the proposed mean imputation procedure,

$$\sqrt{n}(\hat{\mu}^I - \mu) \rightarrow_d N(0, \sigma^2)$$

where “ $\rightarrow_d$ ” denotes “converge in distribution” and σ^2 is given by

$$\sigma^2 = \text{var} \left(\sum_{j=1}^m \frac{1}{p_j} (x_{ij} y_{ij} - \mu_j y_{ij}) \right)$$

Proof:

By Taylor's expansion and Slutsky's theorem, it follows that

$$\begin{aligned} \sqrt{n}(\hat{\mu}^I - \mu) &= \sum_{j=1}^m \sqrt{n} \left(\frac{\frac{1}{n} \sum_{i=1}^n x_{ij} y_{ij}}{\frac{1}{n} \sum_{i=1}^n y_{ij}} - \mu_j \right) \\ &= \sum_{j=1}^m \sqrt{n} \left(\frac{1}{p_j n} \sum_{i=1}^n [(x_{ij} y_{ij} - \mu_j p_j) - \mu_j (y_{ij} - p_j)] \right) \\ &\quad + o_p(1) = \frac{1}{\sqrt{n}} \sum_{j=1}^m \left(\sum_{i=1}^n \frac{1}{p_j} (x_{ij} y_{ij} - \mu_j y_{ij}) \right) \\ &\quad + o_p(1) \rightarrow_d N(0, \sigma^2) \end{aligned}$$

where σ^2 is defined in Theorem 1.

Multiple-Imputation Classes

Assuming there are H imputation classes, let $x_{h,ij}$ be the score of the j th item from the i th subject in the h th imputation class. The quantities $\mu_h, y_{h,ij}, \mu_{h,j}, z_{h,i}, p_{h,j}$ are similarly defined.

For multiple-imputation classes, the parameter of interest is usually a linear combination of μ_h , where $\mu_h = E(x_{h,ij})$. Let w_h denote the coefficient. The parameter of interest is given by

$$\mu = \sum_{h=1}^H w_h \mu_h$$

In clinical research study, μ usually denotes the treatment effect of interest and w_h s are usually the coefficients of contrast satisfying $\sum_h w_h = 0$. For example, in a placebo-controlled clinical trial, the number of imputation classes equals the number of treatment groups, which is two [treatment ($h = 1$) and placebo ($h = 2$)]. w_h s are then chosen to be $w_1 = 1$ and $w_2 = -1$. The parameter of interest is $\mu = \mu_1 - \mu_2$, which is the treatment effect.

For multiple-imputation classes, mean imputation can be carried out within each imputation class. The sample mean of the total score after imputation ($\hat{\mu}_h^t$) is used as an estimator for μ_h . The estimator of μ is given by

$$\hat{\mu}^t = \sum_h w_h \hat{\mu}_h^t \quad (1)$$

Similarly, the following results can be obtained.

Theorem 2. Assuming multiple-imputation classes and $n_h/n \rightarrow p_h$ for some $p_h > 0$, based on the mean imputation procedure described above, we have

$$\sqrt{n}(\hat{\mu}^t - \mu) \rightarrow_d N(0, \sigma^2)$$

Where σ^2 is given by

$$\sigma^2 = \sum_{h=1}^H \frac{w_h^2}{p_h} \text{var} \left(\sum_{j=1}^m \frac{1}{p_{h,j}} (x_{h,ij} y_{h,ij} - \mu_{h,j} y_{h,ij}) \right)$$

Proof:

Similar to the proof of Theorem 1, we have

$$\begin{aligned} \sqrt{n}(\hat{\mu}^t - \mu) &= \sqrt{n} \sum_h w_h (\hat{\mu}_h^t - \mu_h) \\ &= \sum_h \frac{w_h}{\sqrt{n_h} h} \sqrt{n_h} (\hat{\mu}_h^t - \mu_h) \\ &= \sum_h \frac{w_h}{\sqrt{p_h}} \sqrt{n_h} (\hat{\mu}_h^t - \mu_h) + o_p(1) \\ &\rightarrow N \left(0, \sum_h \frac{w_h^2}{p_h} \sigma_h^2 \right) \end{aligned}$$

where σ_h^2 is the asymptotic variance of $\sqrt{n_h}(\hat{\mu}_h^t - \mu_h)$, which can be estimated according to Theorem 1.

STATISTICAL INFERENCE

Variance Estimates

Although the sample variance of $\sum_{j=1}^m (1/p_{h,j})(x_{h,ij} y_{h,ij} - \mu_{h,j} y_{h,ij})$ can be used to estimate its true variance, $p_{h,j}$ and $\mu_{h,j}$ are unknown. One way to overcome this problem is to substitute $p_{h,j}$ and $\mu_{h,j}$ with their consistent estimators (e.g., $x_h^*, \dots, j$ and $1/n \sum_i y_{h,ij}$, respectively). Since this procedure is

based on Taylor's expansion or the linearization of $\hat{\mu}^t$, we denote this estimator by $\hat{\sigma}_{\text{linear}}^2$.

The above procedure is relatively complicated although it requires less computation. As an alternative, the jackknife procedure proposed by Rao and Shao^[7] can be used to estimate the asymptotic variance. Referring to the proofs of Theorem 1 and Theorem 2 in the Appendix, we note that $\hat{\mu}^t$ is the smooth function of $1/n \sum x_{h,ij} y_{h,ij}$ and $1/n \sum y_{h,ij}$. Both of them are sample means of i.i.d. random variables. As a result, Rao and Shao's procedure can be applied here to estimate the asymptotic variance. More specifically, for any given h and i , let $\hat{\mu}_{h,-i}^t$ be an estimate of μ . It can be obtained by first constructing a reduced data set by dropping the i th subject in the h th stratum. Then, perform the proposed mean imputation procedure to the reduced data set. Finally, $\hat{\mu}_{h,-i}^t$ is obtained by (1) but based on the reduced data set. Then, the jackknife estimate of σ^2 is given by

$$\hat{\sigma}_{\text{jack}}^2 = \sum_{h=1}^H \frac{n_h - 1}{n_h} \sum_{i=1}^{n_h} (\hat{\mu}_{h,-i}^t - \hat{\mu}_h^t)^2$$

Testing Hypothesis

In clinical research, the statistical hypotheses of interest can usually be written as

$$H_0: \mu = \mu_0 \quad \text{and} \quad H_1: \mu \neq \mu_0$$

where μ_0 is a prespecified value. One simple example is $\mu_0 = 0$ for a two-group parallel design comparing treatment effects (recall $H = 2$, $w_1 = 1$, and $w_2 = -1$). The test statistic is given by

$$Z = \frac{\hat{\mu}^t - \mu_0}{\hat{\sigma}}$$

where $\hat{\sigma}$ is an estimate for σ . It could be $\hat{\sigma}_{\text{jack}}$ or $\hat{\sigma}_{\text{linear}}$. Refer to the proofs of Theorem 1 and Theorem 2 given in the Appendix. It can be noted that $\hat{\mu}^t$ is a smooth function of $1/n \sum x_{h,ij} y_{h,ij}$ and $1/n \sum y_{h,ij}$, which are sample means of i.i.d. random variables. As a result, according to central limit theorem and Slutsky's theorem, Z is asymptotically normally distributed with mean 0 and variance 1 under the null hypothesis. Therefore, for a given significance level α , the null hypothesis can be rejected if $|Z| > z_{1-\alpha/2}$, where $z_{1-\alpha/2}$ is the $(1 - \alpha/2) \times 100\%$ percentile of a standard normal distribution.

A Simulation Study

A simulation study was conducted to evaluate the finite sample performance of the proposed method. The objective of the simulation study is multifold. It includes the following.

1. Note that the estimators derived by both imputation and complete units are consistent for μ . As a result, it is of interest to compare their relative efficiency in terms of standard deviation.
2. Two methods (linearization and jackknife) are proposed for estimation of the standard deviation of $\hat{\mu}'$. Although they are asymptotically equivalent to each other, it is of interest to compare their finite sample performance by comparing them with the true standard deviation.
3. The proposed Z-test for the hypothesis of interest is based on large sample theory. As a result, the empirical significance level of the test may not be exactly the same as the nominal level. Therefore, it is of interest to evaluate the finite sample performance of the proposed Z-test based on both $\hat{\sigma}_{\text{linear}}$ and $\hat{\sigma}_{\text{jack}}$.

Consider a two-arm parallel randomized clinical trial comparing a test treatment with a placebo. There are two imputation classes ($H = 2$), $w_1 = 1$, $w_h = -1$, and the parameter of interest is the treatment effect $\mu = w_1\mu_1 + w_2\mu_2 = \mu_1 - \mu_2$.

For illustration purposes and for the sake of convenience, we fix $m = 5$ and $n = 20$, which means there are a total of 20 items (questions), and for each question the rating score ranges from 1 to 5. We also assume the score of each item is marginally distributed with probabilities of 0.3, 0.1, 0.3, 0.1, and 0.2. Note that it is not necessary for each item to have the same sample space and the same distribution.

Let n_1 and n_2 denote the sample sizes for group 1 and group 2, respectively. They range from 20 to 40. For a given subject, we first generate a continuous standard uniform random number U_0 . For any $j \leq n$, we generate another standard uniform random number R_j independent of U_0 . Then, define $U_j = U_0$ if $R_j \leq 0.5$. Otherwise, let U_j be another standard uniform random number independent of both U_0 and R_j . Compare U_j with the cumulative distribution function of the score of the item to determine the value of the j th item. More specifically,

$$x_{h,j} = \begin{cases} 1 & \text{if } U_j \leq 0.3 \\ 2 & \text{if } 0.3 < U_j \leq 0.4 \\ 3 & \text{if } 0.4 < U_j \leq 0.7 \\ 4 & \text{if } 0.7 < U_j \leq 0.8 \\ 5 & \text{if } 0.8 < U_j \end{cases}$$

where “ $\Leftarrow$ ” means “defines to be.” There are two important properties of $x_{h,j}$ generated by this procedure. First, U_j is still a marginally standard uniform random variable. As a result, $x_{h,j}$ is distributed with probabilities of 0.3, 0.1, 0.3, 0.1, and 0.2. Second, all the U_j from the same subject have probability 0.5 to share the same U_0 . Consequently, they are correlated. The purpose of this is to reflect the

fact that the observations from the same subject should be correlated in some way.

In order to determine if the score of an item is missing or not, we generate a standard uniform random variable U_0 for each subject. Generate another standard uniform random variable R_j for each $j \leq n$. Then, define $U_j = U_0$ if $R_j \leq 0.5$. Otherwise, let U_j be another standard uniform random number independent of both U_0 and R_j . Then, the score of the j th item is set to be missing if $U_j > p_h$ otherwise it is observed, where p_h is a prespecified value. As a result, for a given item, it has a marginal probability p_h to be observed. In the simulation, we consider p_h to be 0.80, 0.85, 0.90, 0.95, and 1.00. As a result, the missing of all items from the same subject are correlated with each other but independent of the value of the item.

For a given set of parameters (n_1 , n_2 , p_h), 10,000 simulation runs were carried out. For each simulation, a data set mimics a two-arm parallel trial, and is generated according to the specified parameters. For the generated data set, μ is estimated by both imputation method ($\hat{\mu}'$) and complete units only ($\hat{\mu}$). Their sample means are reported. Their sample standard deviations are used as estimates for their true standard deviation. For the same data set, both jackknife and linearization methods are used to estimate the standard deviation of $\hat{\mu}'$. Their sample means are used to estimate the true values of those two estimates. For the same data set, the Z-tests are performed by using both $\hat{\sigma}_{\text{jack}}$ and $\hat{\sigma}_{\text{linear}}$. The empirical p value is estimated by the proportion of the data sets rejecting the null hypothesis. Table 1 summarizes the simulation results.

Table 1 findings are summarized below.

1. The efficiency (in terms of standard deviation) of the point estimate based on imputed data is improved as compared with the method of using the completers only.
2. Both jackknife and linearization provide reasonably good estimates for the standard deviation of $\hat{\mu}'$. The jackknife estimator seems to perform slightly better than the estimate obtained by linearization.
3. The empirical level of both Z-tests are reasonably close to the nominal level 5%. However, the Z-test using $\hat{\sigma}_{\text{jack}}$ is slightly better than the Z-test using $\hat{\sigma}_{\text{linear}}$.

AN EXAMPLE

To illustrate the application of the proposed mean imputation with item nonrespondents, consider an example concerning the study of treatment effect on controlling agitated behavior of a drug product in schizophrenic patients and patients with schizoaffective disorders. A randomized, parallel-group clinical trial comparing two treatments was conducted in patients with mild to moderate schizophrenia or schizoaffective disorder to help control their agitated behavior. Twenty patients were randomized and completed

the study of 12 weeks. An instrument consisting of 20 items was used to quantitate the patient's agitated behavior. The scale of each item ranges from 1 (none) to 5 (severe). The results at endpoint are given in Table 2.

Although, the trial recruited 20 patients for each treatment group, there were only eight unit respondents per group. The analysis based on complete units estimates the treatment effect $\hat{\mu} = -3.875$ with standard deviation $\hat{\sigma} = 5.662$. The corresponding Z statistic is given by $Z = 3.875/5.662 = -0.684$. The p value is given by 0.494, which is not significant (< 0.05).

On the other hand, the analysis based on the proposed mean imputation approach estimates the treatment effect $\hat{\mu}' = -10.767$ with standard deviation $\hat{\sigma}_{\text{jack}} = 4.862$ and $\hat{\sigma}_{\text{linear}} = 4.859$. The corresponding Z statistics are given by 2.214 and 2.216, respectively, with p values given by 0.027 and 0.027, respectively, which are significant.

In this example, the analysis based on unit respondents only may lose too much power/efficiency and consequently may be misleading. The mean imputation approach, on the other hand, is more efficient than the analysis using complete units.

*indicates missing value.

No = subject number.

TRT = treatment group.

Complete denotes whether the unit is complete (1, complete and 0, not complete).

CONCLUSION

In summary, we propose a mean imputation approach to handle item nonrespondents when the total score is the parameter of interest. The derived estimator is consistent and asymptotically normal. The jackknife method is useful for estimation of the standard deviation of the proposed estimator. The proposed method is not only statistically valid but also more efficient as compared with the method based on complete units only.

Abstract

This entry summarizes the most commonly used imputation methods and investigates their statistical properties, and also discusses recent developments.

INTRODUCTION

Missing values or incomplete data are commonly encountered in clinical research and are studied by many authors.^[1–3] Basically, the causes of missing values in a study can be classified into two categories. The first category includes the reasons that are not directly related to the study. For example, a patient may be lost to follow-up because he/she moves out of the area. This category of missing values can be considered as *missing completely at random*. The second category includes the reasons that are related to the study. For example, a patient may withdraw from the study due to treatment-emergent adverse events. In practice, it is not uncommon to have multiple assessments from each subject. Subjects with all observations missing are called unit nonrespondents. Because unit nonrespondents do not provide any useful information, these subjects are usually excluded from the analysis. On the other hand, the subjects with some, but not all, observations missing are referred to as item nonrespondents. In practice, excluding item nonrespondents from the analysis is considered against the *intent-to-treat* (ITT) principle and, hence, not acceptable. In clinical research, the primary analysis is usually conducted based on ITT population, which includes all randomized subjects with at least posttreatment evaluation. As a result, most item nonrespondents may be included in the ITT population. In practice, excluding item nonrespondents may seriously decrease power/efficiency of the study.

To account for item nonrespondents, two methods are commonly considered. The first method is the so-called likelihood-based method. Under a parametric model, the marginal likelihood function for the observed responses is obtained by integrating out the missing responses. The parameter of interest can then be estimated by the maximum likelihood estimator (MLE). Consequently, a corresponding test (e.g., likelihood ratio test) can be constructed. The merit of this method is that the resulting statistical procedures are usually efficient. The drawback

is that the calculation of the marginal likelihood could be difficult. As a result, some special statistical or numerical algorithms are commonly applied for obtaining the MLE. For example, the expectation-maximization (EM) algorithm is one of the most popular methods for obtaining the MLE when there are missing data. The other method for item nonrespondents is imputation. Compared with the likelihood-based method, the method of imputation is relatively simple and easy to apply. The idea of imputation is to treat the imputed values as the observed values and then apply the standard statistical software for obtaining consistent estimators. However, it should be noted that the variability of the estimator obtained by imputation is usually different from the estimator obtained from the complete data. In this case, the formulas designed to estimate the variance of the complete data set cannot be used to estimate the variance of estimator produced by the imputed data. As an alternative, two methods are considered for estimation of its variability. One is based on Taylor's expansion. This method is referred to as the "linearization method." The merit of the linearization method is that it requires less computation. However, the drawback is that its formula could be very complicated and/or nontrackable. The other approach is based on resampling method (e.g., bootstrap and jackknife). The drawback of the resampling method is that it requires an intensive computation. The merit is that it is very easy to apply. With the help of a fast-speed computer, the resampling method has become much more attractive in practice.

Note that imputation is not only popular in clinical research, it is also very popular in many other statistical fields such as sample survey. However, the imputation methods in clinical research are more diversified due to the complexity of the study design relative to sample survey. As a result, the statistical properties of many commonly used imputation methods in clinical research are still unknown, while most imputation methods used in sample survey are well studied. Hence, the imputation methods in clinical research provide a unique challenge

and also an opportunity for the statisticians in the area of clinical research. In what follows, we will summarize the most commonly used imputation methods and investigate their statistical properties. Recent development will also be discussed.

LAST OBSERVATION CARRY FORWARD/ENDPOINT ANALYSIS

Last observation carry forward (LOCF) and endpoint analysis (EPA) are probably the most commonly used imputation methods in clinical research. For illustration purposes, one example is described below.

Consider a randomized, parallel-group clinical trial comparing r treatments. Each patient is randomly assigned to one of the treatments. According to the protocol, each patient should undergo s consecutive visits. Let y_{ijk} be the observation from the k th subject in the i th treatment group at visit j . The following statistical model is usually considered.

$$y_{ijk} = \mu_{ij} + \epsilon_{ijk}, \text{ where } \epsilon_{ijk} \sim N(0, \sigma^2) \quad (1)$$

where μ_{ij} represents the fixed effect of the i^{th} treatment at visit j . If there are no missing values, the primary comparison between treatments will be based on the observations from the last visit ($j = s$) because this reflects the treatment difference at the end of the treatment period. However, it is not necessary that every subject completes the study. Suppose that the last evaluable visit $j^* < s$ for the k th subject in the i th treatment group. Then the value of y_{ij^*k} can be used to impute t_{isk} . After imputation, the data at endpoint are analyzed by the usual analysis of variance (ANOVA) model. We will refer to the procedure described above as LOCF.

Note that the method of LOCF is usually applied according to the ITT principle. The ITT population include all randomized subjects. In clinical research, although the LOCF is commonly employed, the statistical motivation and the consequence are not clear. In what follows, we attempt to provide two different approaches to understand the statistical properties of LOCF.

Bias-Variance Trade-Off

The objective of a clinical study is usually to assess the safety and efficacy of a test treatment under investigation. Statistical inferences on the efficacy parameters are usually obtained. In practice, a sufficiently large number of sample size is required to obtain a reliable estimate and to achieve a desired power for establishment of the efficacy of the treatment. The reliability of an estimator can be evaluated by bias and by variability. A reliable estimator should have a small or zero bias with small variability. Hence, the estimator based on LOCF and the estimator

based on completers are compared in terms of their bias and variability.

For illustration purposes, we focus on only one treatment group with two visits. Assume that there are a total of $n = n_1 + n_2$ randomized subjects, where n_1 subjects complete the trial, while the remaining n_2 subjects only have observations at visit 1. Let y_{ik} be the response from the k th subject at the i th visit and $\mu_i = E(y_{ik})$. The parameter of interest is μ_2 . The estimator based on completers is given by

$$\bar{y}_c = \frac{1}{n_1} \sum_{k=1}^{n_1} y_{i2k}$$

On the other hand, the estimator based on LOCF can be obtained as

$$\bar{y}_{\text{LOCF}} = \frac{1}{n} \left(\sum_{i=1}^{n_1} y_{i2k} + \sum_{i=n_1+1}^n y_{i1k} \right)$$

It can be verified that the bias of $\bar{y}_c$ is 0 with variance $\sigma^2 = n_1$, while of the bias of $\bar{y}_{\text{LOCF}}$ is $n_2(\mu_1 - \mu_2)/n$ with variance $\sigma^2/(n_1 + n_2)$.

As noted, although LOCF may introduce some bias, it decreases the variability. In a clinical trial with multiple visits, usually, $\mu_j \approx \mu_s$ if $j \approx s$. This implies that the LOCF is recommended if the patients withdraw from the study at the end of the study. However, if a patient drops out of the study at the very beginning, the bias of the LOCF could be substantial. As a result, it is recommended that the results from the analysis based on LOCF be interpreted with caution.^[4]

Hypothesis Testing

In practice, the LOCF is viewed as a pure imputation method for testing the null hypothesis of

$$H_0 : \mu_{1s} = \dots = \mu_{rs}$$

where μ_{ij} are defined in Eq. 1.

Shao and Zhong^[5] provided another look of statistical properties of the LOCF under the above null hypothesis. More specifically, they partitioned the total patient population into s subpopulations according to the time when the number of patients drop out from the study. Note that in their definition, the patients who complete the study are considered a special case of “drop out” at the end of the study. Then μ_{ij} represents the population mean of the j th subpopulation under treatment i . Assume that the j th subpopulation under the i th treatment accounts for $p_i \times 100\%$ of the overall population under the i th treatment. They argue that the objective of the intend-to-treat analysis is to test the following hypothesis test

$$H_0 : \mu_1 = \dots = \mu_r \quad (2)$$

where $\mu_i = \sum_j^s 1 p_{ij} \mu_{ij}$. Based on the above hypothesis, Shao and Zhong^[5] indicated that the LOCF bears the following properties:

1. In the special case of $r = 2$, the asymptotic ($n_i \rightarrow \infty$) size of the LOCF under H_0 is $\leq \alpha$ if and only if

$$\lim \left(\frac{n_2 \tau_1^2}{n} + \frac{n_1 \tau_2^2}{n} \right) \leq \lim \left(\frac{n_1 \tau_1^2}{n} + \frac{n_2 \tau_2^2}{n} \right)$$

where

$$\tau_i^2 = \sum_{j=1}^s p_{ij} (\mu_{ij} - \mu_i)^2$$

The LOCF is robust in the sense that its asymptotic size is α if $\lim(n_1/n) = (n_2/n)$ or $\tau_1^2 = \tau_2^2$. Note that, in reality, $\tau_1^2 = \tau_2^2$ is impractical unless $\mu_{ij} = \mu_i$ for all j . However, $n_1 = n_2$ (as a result $\lim(n_1/n) = \lim(n_2/n)$) is very typical, in practice. The above observation indicates in such a situation ($n_1 = n_2$) that LOCF is still valid.

2. When $r = 2$, $\tau_1^2 \neq \tau_2^2$, and $n_1 \neq n_2$, the LOCF has an asymptotic size smaller than α if $(n_2 - n_1)\tau_1^2 < (n_2 - n_1)\tau_2^2$ or larger than α if “ $<$ ” in Eq. 3 is replaced by “ $>$.”
3. When $r \geq 3$, the asymptotic size of the LOCF is generally not α except for some special case (e.g., $\tau_1^2 = \tau_2^2 = \dots = \tau_r^2 = 0$).

Because the LOCF usually does not produce a test with asymptotic significance level α when $r \geq 3$, Shao and Zhong^[5] proposed the following testing procedure based on the idea of poststratification. The null hypothesis H_0 should be rejected if $T > \chi_{1-\alpha, r-1}^2$, where $\chi_{1-\alpha, r-1}^2$ is the $(1 - \alpha)$ th quantile of a chi-square random variable With $r - 1$ degrees of freedom and

$$T = \sum_{i=1}^r \frac{1}{\hat{V}_i} \left(\bar{y}_{i-} - \frac{\sum_{i=1}^r \bar{y}_{i-} / \hat{V}_i}{\sum_{i=1}^r 1 / \hat{V}_i} \right)^2$$

$$\hat{V}_i = \frac{1}{n_i(n_i - 1)} \sum_{j=1}^s \sum_{k=1}^{n_{ij}} (y_{ijk} - \bar{y}_{i-})^2$$

Under the Eq. model 1 and the null hypothesis of 2, this procedure has the exact type I error α .

MEAN/MEDIAN IMPUTATION

Missing ordinal responses are also commonly encountered in clinical research. For those types of missing data, mean or median imputation is commonly considered. Let x_i be the ordinal response from the i th subject, where $i = 1, \dots, n$. The parameter of interest is $\mu = E(x_i)$. Assume that x_i for $i = 1, \dots, n_1 < n$ are observed and the rest are missing.

Median imputation will impute the missing response by the median of the observed response (i.e., x_i , $i = 1, \dots, n_1$). The merit of median imputation is that it can keep the imputed response within the sample space as the original response by appropriately defining the median. The sample mean of the imputed data set will be used as an estimator for the population mean. However, as the parameter of interest is population mean, the median imputation may lead to biased estimates.

As an alternative, mean imputation will impute the missing value by the sample mean of the observed units (i.e., $1/n_1 \sum_{i=1}^{n_1} x_i$). The disadvantage of the mean imputation is that the imputed value may be out of the original response sample space. However, it can be shown that the sample mean of the imputed data set is a consistent estimator of population mean. Its variability can be assessed by jackknife method proposed by Rao and Shao.^[6]

In practice, usually, each subject will provide more than one ordinal response. The summation of those ordinal responses (total score) is usually considered as the primary efficacy parameter. The parameter of interest is the population mean of the total score. In such a situation, mean/median imputation can be carried out for each ordinal response within each treatment group.

REGRESSION IMPUTATION

The method of regression imputation is usually considered when covariates are available. Regression imputation assumes a linear model between the response and the covariates. The method of regression imputation has been studied by various authors.^[7,8]

Let y_{ijk} be the response from the k th subject in the i th treatment group at the j th visit. The following regression model is considered:

$$y_{ijk} = \mu_i + \beta_i x_{ij} + \epsilon_{ijk} \quad (3)$$

where x_{ij} is the covariate of the k th subject in the i th treatment group. In practice, the covariates x_{ij} could be demographic variables (e.g., age, sex, and race) or patient's baseline characteristics (e.g., medical history or disease severity). Model 4 suggests a regression imputation method. Let $\hat{\mu}_i$ and $\hat{\beta}_i$ denote the estimators of μ_i and β_i based on complete data set, respectively. If y_{ijk} is missing, its predicted mean value $y_{ijk}^* = \hat{\mu}_i + \hat{\beta}_i x_{ij}$ is used to impute. The imputed values are treated as true responses and the usual ANOVA is used to perform the analysis.

MARGINAL/CONDITIONAL IMPUTATION FOR CONTINGENCY TABLES

In an observational study, two-way contingency tables can be used to summarize two-dimensional categorical data.

Each cell (category) in a two-way contingency table is defined by a two-dimensional categorical variable (A, B) , where A and B take values in $\{1, \dots, a\}$ and $\{1, \dots, b\}$ respectively. Sample cell frequencies can be computed based on the observed responses of (A, B) from a sample of units (subjects). Statistical interest includes the estimation of cell probabilities and testing hypotheses of goodness of fit or the independence of the two components A and B . In an observational study, there can be more than one strata. It is assumed that within a strata, sampled units independently have the same probability π_A to have missing B and observed A , π_B to have missing A and observed B , π_C to have observed A and B . (The probabilities π_A , π_B , and π_C may be different in different imputation classes.) As units with both A and B missing are considered as unit nonrespondent, they are excluded in the analysis. As a result, without loss of generality, it is assumed that $\pi_A + \pi_B + \pi_C = 1$.

For a two-way contingency table, it is very important for an appropriate imputation method to keep imputed values in the appropriate sample space. Whether in calculating the cell probability or in testing hypotheses (e.g., testing independence or goodness of fit), the corresponding statistical procedures are all based on the frequency counts of a contingency table. If the imputed value is out of the sample space, additional categories will be produced which is of no practical meaning. As a result, two hot deck imputation methods are thoroughly studied by Shao and Wang.^[9]

Simple Random Sampling

Consider a sampled unit with observed $A = i$ and missing B . Two imputation methods were studied by Shao and Wang.^[8] The marginal (or unconditional) random hot deck imputation method imputes B by the value of B of a unit randomly selected from all units with observed B . The conditional hot deck imputation method imputes B by the value of B of a unit randomly selected from all units with observed B and $A = i$. All nonrespondents are imputed independently.

Point Estimation

After imputation, the cell probabilities p_{ij} can be estimated using the standard formulas in the analysis of data from a two-way contingency table by treating imputed values as observed data. Denote these estimators by $\hat{p}_{ij}^I$ where $i = 1, \dots, a$, and $j = 1, \dots, b$. Let

$$\hat{p}^I = (\hat{p}_{11}^I, \dots, \hat{p}_{1b}^I, \dots, \hat{p}_{a1}^I, \dots, \hat{p}_{ab}^I)'$$

and

$$p = (p_{11}, \dots, p_{1b}, \dots, p_{a1}, \dots, p_{ab})'$$

where $p_{ij} = P(A = i, B = j)$. Intuitively, marginal random hot deck imputation leads to consistent estimators of $p_i = P(A = i)$ and $p_j = P(B = j)$, but not p_{ij} . Shao and

Wang^[8] showed that $\hat{p}^I$ under conditional hot deck imputation are consistent, asymptotically unbiased, and asymptotically normal.

Theorem 1. Assume that $\pi_C > 0$. Under conditional hot deck imputation,

$$\sqrt{n}(\hat{p}^I - p) \rightarrow_d N(0, MPM' + (1 - \pi_C)P)$$

Where $P = \text{diag}\{p\} = pp'$ ($\text{diag}\{a\}$ is a diagonal matrix whose i th diagonal element is the i th component of the vector a),

$$M = \frac{1}{\sqrt{\pi_C}} \left(I_{a \times b} - \pi_A \text{diag}\{p_{B|A}\} I_a \otimes U_b \right) - \pi_B \text{diag}\{p_{A|B}\} U_a \otimes I_b,$$

$$p_{A|B} = (p_{11}/p_{.1}, \dots, p_{1b}/p_{.b}, \dots, p_{a1}/p_{.1}, \dots, p_{ab}/p_{.b})',$$

$$p_{B|A} = (p_{11}/p_{1.}, \dots, p_{1b}/p_{1.}, \dots, p_{a1}/p_{a.}, \dots, p_{ab}/p_{a.})'$$

Where I_a denotes an a -dimensional identity matrix, U_b denotes a b -dimensional square matrix with all components being 1, and $\otimes$ is the Kronecker product.

Goodness-of-Fit Test

A direct application of Theorem 1 is to obtain a Wald-type test for goodness of fit. Consider the null hypothesis of the form $H_0: p = p_0$, where p_0 is a known vector. Under H_0 ,

$$X_W^2 = n(\hat{p}^* - p_0^*)' \Sigma^{*-1} (\hat{p}^* - p_0^*) \rightarrow_d \chi_{ab-1}^2$$

where χ_v^2 denotes a random variable having the chi-square distribution with v degrees of freedom, $\hat{p}^*(p_0^*)$ is obtained by dropping the last component of $\hat{p}^I(p_0)$, and $\hat{\Sigma}^*$ is the estimated asymptotic covariance matrix of $\hat{p}^*$, which can be obtained by dropping the last row and column of $\hat{\Sigma}$, the estimated asymptotic covariance matrix of $\hat{p}^I$.

Noting the fact that the computation of $\hat{\Sigma}^{*-1}$ is complicated, Wang and Shao proposed a simple correction of the standard Pearson chi-square statistic by matching the first-order moment, an approach developed by Rao and Scott.^[10] Let

$$X_G^2 = n \sum \frac{(\hat{p}_{ij}^I - p_{ij})^2}{p_{ij}}$$

It is noted that under conditional imputation the asymptotic expectation of X_G^2

$$\frac{1}{\pi_C} (ab + \pi_A^2 a + \pi_B^2 b - 2\pi_A a - 2\pi_B b - 2\pi_A \pi_B + 2\pi_A \pi_B \delta) - \pi_C ab + (ab - 1)$$

Let (see equation at bottom of the page below). Then the asymptotic expectation of X_G^2/λ is $ab - 1$, which is the first-order moment of a standard chi-square variable with $ab - 1$ degrees of freedom. Thus, X_G^2/λ can be used just like a normal chi-square statistic to test the goodness of fit. However, it should be noted that this is just an approximated test procedure which is not asymptotically correct.

According to a Shao and Wang's simulation study, this test performs reasonably well with moderate sample sizes.

TESTING FOR INDEPENDENCE

Testing for the independence between A and B can be performed by the following chi-square statistic when there is no missing data

$$X^2 = n \sum_{ij} \frac{(\hat{p}_{ij}^I - \hat{p}_i^I \hat{p}_j^I)^2}{\hat{p}_i^I \hat{p}_j^I} \rightarrow d \chi_{(a-1)(b-1)}^2$$

It is of interest to know what the asymptotic behavior of the above chi-square statistic is under both marginal and conditional imputation. It is found that under the null hypothesis of A and B are independent and conditional hot deck imputation

$$X^2 \rightarrow d(\pi_C^{-1} + 1 - \pi_C) \chi_{(a-1)(b-1)}^2$$

and under marginal hot deck imputation

$$X_{MI}^2 \rightarrow d \chi_{(a-1)(b-1)}^2$$

Results Under Stratified Simple Random Sampling

When Number of Strata is Small

Stratified samplings are also commonly used in medical study. For example, a large epidemiology study is usually conducted by several large centers. Those centers are usually considered as strata. For those types of study, the number of strata is not very large; however, the sample size within each strata is very large. As a result, imputation is usually carried out within each strata.

Within the h th stratum, we assume that a simple random sample of size n_h is obtained and samples across strata are obtained independently. The total sample size is $n = \sum_{h=1}^H n_h$ where H is the number of strata and n_h is the sample size in stratum h . The parameter of interest is the overall cell probability vector $p = \sum_{h=1}^H w_h p_h$, where w_h is the h th stratum weight. The estimator of p based on conditional imputation is given by $\hat{p}^I = \sum_{h=1}^H w_h \hat{p}_h^I$. Assume that $n_h = n \rightarrow p$ as $n \rightarrow \infty$, $h = 1, \dots, H$. Then a direct application of Theorem 1 leads to

$$\sqrt{n}(\hat{p}^I - p) \rightarrow d N(0, \Sigma)$$

where

$$\Sigma = \sum_{h=1}^H \frac{w_h^2}{p_h} \Sigma_h$$

and Σ_h is the Σ in Theorem 1 but restricted to the h th stratum.

When Number of Strata is Large

In a medical survey, it is also possible to have the number of strata (H) very large, while the sample size within each strata is small. A typical example is that if a medical survey is conducted by family, then the family can be considered as a strata and all the members within the family become the samples from this strata. In such a situation, the method of imputation within stratum is impractical because it is possible that within a stratum, there are no completers. As an alternative, Wang and Shao^[9] proposed the method of imputation across strata under the assumption that $(\pi_{hA}, \pi_{hB}, \pi_{hC})$, where $h = 1, \dots, H$, is constant. More specifically, let $n_{h,ij}^C$ denote the number of completers in the h th stratum such that $A = i$ and $B = j$. For a sampled unit in the k th imputation class with observed $B = j$ and missing A , the missing value is imputed by i according to the conditional probability

$$p_{ij} \Big| B, k = \frac{\sum_h w_h n_{h,ij}^C / n_h}{\sum_h w_h n_{h,j}^C / n_h}$$

Similarly, the missing value of a sampled unit in the k th imputation class with observed $A = i$ and missing B can be imputed by j according to the conditional probability

$$p_{ij} \Big| A, k = \frac{\sum_h w_h n_{h,ij}^C / n_h}{\sum_h w_h n_{h,i}^C / n_h}$$

Again, $\hat{p}^I$ can be computed by ignoring imputation classes and treating imputed values as observed data. The following result establishes the asymptotic normality of

$$\lambda = \frac{\frac{1}{\pi_C} (ab + \pi_A^2 a + \pi_B^2 b - 2\pi_A a - 2\pi_B b - 2\pi_A \pi_B + 2\pi_A \pi_B \delta) + (ab - 1)}{ab - 1}$$

based on the method of conditional hot deck imputation across strata.

Theorem 2. Let $(\pi_{hA}, \pi_{hB}, \pi_{hC}) = (\pi_A, \pi_B, \pi_C)$ for all h . Assume further that $H \rightarrow \infty$ and that there are constants c_j for $j = 1, \dots, 4$, such that $n_h \leq c_1$, $c_2 \leq H w_h \leq c_3$, and $p_{h,ij} > c_4$ for all h . Then

$$\sqrt{n}(\hat{p}^I - p) \rightarrow d N(0, \Sigma)$$

where Σ is the limit of

$$n \left(\sum_h \frac{w_h^2}{n_h} \Sigma_h + \Sigma_A + \Sigma_B \right)$$

Details regarding the expression of $\Sigma_h, \dots, \Sigma_A$, and Σ_B and their procedure can be found in Wang.^[9]

CONCLUSION

Missing values or incomplete data are commonly encountered in clinical research. How to handle the incomplete data is always a challenge to the statisticians in practice. Imputation as one of very popular methodology to compensate for the missing data is widely used in biopharmaceutical research. As compared to its popularity, however, its theoretical properties are far away from well understood. Further research is needed. More information regarding the prevention and treatment of missing data in clinical trials can be found in.^[11]

Abstract

It is widely recognized that, as opposed to *in vivo*, *in vitro* methods are less variable, easier to control, and more likely to detect differences between products if they exist. This entry details several analysis methods for *in vitro* bioequivalence testing as well as discussing some of the difficulties associated with profile analysis.

INTRODUCTION

Bioequivalence testing is considered as a surrogate for the clinical evaluation of the therapeutic equivalence of drug products based on the *Fundamental Bioequivalence Assumption* that when two drug products (e.g., a brand name drug and its generic copy) are equivalent in bioavailability, they will reach the same therapeutic effect.^[1]

In other words, two drugs are called bioequivalent if they are equivalent in bioavailability. In practice, most drugs' active moiety is absorbed into the blood system before it takes action. As a result, the pharmacokinetic (PK) parameters taken from the bloodstream—such as the area under the plasma concentration curve (AUC), the maximum concentration ($C_{\max}$), and the time to the maximum concentration ($T_{\max}$)—are usually considered to characterize the bioavailability of the drug. This type of bioequivalence is called *in vivo* bioequivalence. However, for some locally acting drug products, such as nasal aerosols (e.g., metered dose inhalers) and nasal sprays (e.g., metered dose spray pumps) that are not intended to be absorbed into the bloodstream, bioavailability may be assessed by measurements intended to reflect the rate and the extent to which the active ingredient or active moiety becomes available at the site of action. For these local delivery drug products, the U.S. Food and Drug Administration (FDA) indicates that bioequivalence may be assessed, with suitable justification, by *in vitro* bioequivalence studies alone (21 CFR 320.24). Although it is recognized that *in vitro* methods are less variable, easier to control, and more likely to detect differences between products if they exist, the clinical relevance of the *in vitro* tests or the magnitude

of the differences in the tests is not clearly established until a guidance on bioavailability and bioequivalence studies for nasal aerosols and nasal sprays for local action has been issued by the FDA.^[2]

STUDY DESIGN AND DATA COLLECTION

For the assessment of *in vitro* bioequivalence, the 1999 FDA guidance^[2] requires that *in vitro* testing of emitted dose uniformity, droplet size distribution, spray pattern, plume geometry, priming/repriming, and tail-off profile be done to demonstrate comparable delivery characteristics between two drug products. However, the 2003 FDA draft guideline^[3] indicates that *in vitro* bioequivalence can be established through the following tests for single actuation content through container life, droplet size distribution by laser diffraction, drug in small particles/droplets, or particle/droplet size distribution by cascade impactor, drug particle size distribution by microscopy, spray pattern, plume geometry, and priming and re-priming. In this section, a brief description of study design and some of these tests are given.

Study Design

According to the FDA,^[2] three lots/sublots from each product are required to be tested for *in vitro* emitted dose uniformity, droplet size distribution, spray pattern, plume geometry, priming/repriming, and tail-off profile. For each *in vitro* test, 10 samples are randomly drawn from each lot. Samples are randomized for *in vitro* tests. The analysts will

not have access to the randomization codes. An automated actuation station with a fixed settings (actuation force, dose time, return time, and hold time) is usually used for the *in vitro* tests.

Priming, Emitted Dose Uniformity, Priming/Repriming, and Tail-Off Profile

Based on the FDA comment, the priming, emitted dose uniformity, priming/repriming, and tail-off tests may be tested in the following setting. Three individual lots of test product and reference product are evaluated. For each lot, 10 samples are then tested for pump priming, unit spray content through life, and tail-off studies. Then additional samples for each lot are evaluated for the prime hold study (reprime study).

For each sample unit, spray samples are collected for sprays 1–8 and analyzed in order to determine the minimum number of actuations required before the pump delivers the labeled dose of drug (sprays 1–8). To characterize emitted dose uniformity at the beginning of unit life, spray 9 is collected. Sprays 10–15 are wasted by the automatic actuation station. Spray 16 is collected in the middle of unit life. Sprays 17–20 are wasted. Sprays 21–23 are collected at the end of the unit life. Additional sprays after spray 23 are collected and analyzed to determine the tail-off profile.

Ten additional samples are drawn randomly from each lot of drug product for the pump prime hold study. For each unit, the first 12 sprays (sprays 1–12) are wasted. Sprays 13 and 14 are collected as fully primed sprays. The unit is then stored undisturbed for 24 hr. Within each lot, five samples are placed in the upright position while the other five are placed in a side position. After that, sprays 15–17 are collected. The unit is then stored undisturbed in its former position for another 24 hour. After that, the doses emitted by sprays 18–20 are collected. All spray samples are weighted in order to obtain repriming characteristics.

Spray Pattern

A spray pattern produced by a nasal spray pump evaluates in part the integrity and the performance of the orifice and pump mechanism in delivering a dose to its intended site of deposition. Measurements can be made on the diameter of the horizontal intersection of the spray plume at different distances from the actuator tip. Spray patterns are usually measured at three distances (e.g., 1, 2, and 4 cm) at both the beginning (sprays 8–10) and the end (sprays 17–19) of unit life. As a result, a total of six spray patterns is collected for each sample unit. For each spray pattern image, the diameters (the longest and shortest diameters) and the ovality (which is defined by the ratio of the longest to the shortest diameters) are measured.

Droplet Size Distribution

For a test of droplet size distribution, methods of laser diffraction and cascade impaction are commonly used. These methods are briefly described below.

Laser Diffraction

For a test of droplet size distribution using laser diffraction particle analyzer, each sample unit is first primed by actuating the pump eight times using an automatic actuation station. Droplet size distribution is then determined at three distances (e.g., 3, 5, and 7 cm) from the laser beam and at the beginning, the middle, and the end of unit life. At each distance, three measurements of delay times (plume formation, start of dissipation, and intermediate measurements) and overall evaluation are used to characterize the droplet size. As a result, a total of 36 measurements is recorded for each sample unit.

Cascade Impaction Technique

When the spray pump is actuated in the nasal cavity, a fine mist of droplets is generated. Droplets that are $>9 \mu\text{m}$ in diameter are considered nonrespirable and are therefore useful for nasal deposition. As recommended in the FDA 1999 Guidance, the data should be reported as follows:

- Group 1: Adaptor (expansion chamber, i.e., 5-L flask), rubber gasket, throat, and Stage 0.
- Group 2: Stage 1.
- Group 3: Stage 2 to filter.

Each sample unit is first primed by actuating the pump seven times using an automatic actuation station. Droplet size distribution is then determined at the beginning and the end of the life of the sample. Thus a total of six groups of results is reported for each spray unit.

Plume Geometry

Plume geometry is performed on the nasal spray plume that is allowed to develop into an unconstrained space that far exceeds the volume of nasal cavity. It represents a frozen moment in spray plume development that is viewed from two axes perpendicular to the axis of plume development. The samples should be actuated vertically. Prime the pump with 10 actuations until a steady fine mist is produced from the pump. A fast-speed video camera is placed in front of the sample bottle and starts recording. Repeat the test by rotating the actuator 90° to the previous actuator placement so that two side views are at 90° to each other (two perpendicular planes) and, relative to the axis of the plume of the spray, are captured when actuated into space.

Spray plumes are characterized at three stages: early upon formation, as the plume starts dissipate, and at some intermediate time. Longest vertical distance (LVD), widest horizontal distance (WHD), and plume angle (ANG) are recorded and analyzed.

REGULATORY REQUIREMENTS AND STATISTICAL METHODS

Noncomparative Analysis

For each *in vitro* test, the FDA requires that a noncomparative analysis be performed. Noncomparative analysis refers to the statistical summarization of the bioavailability data by descriptive statistics. As a result, means, standard deviations, and coefficients of variation (CVs) in percentage of the six *in vitro* tests should be documented. More specifically, the overall sample means for a given formulation should be averaged over all samples (e.g., bottles/canisters), life stages (except for priming and repriming evaluations), and lots or batches. In addition to the overall means, means at each life stage for each batch averaged over all bottles/canisters and for each life stage averaged over all lots (or batches) should be presented. For profile data, means, standard deviations, and percent CVs should be reported for each stage. The between-lot (or batch), within-lot (or batch) between-sample (e.g., bottle or canister), and within-sample (e.g., bottle or canister) between-life stage variability should be evaluated through appropriate statistical models.

Bioequivalence Limit

The following formula is given in the 1999 FDA redetermining the bioequivalence (BE) limit

$$\frac{(\text{average BE limit in natural log scale})^2 + \text{variance terms of offset}}{\text{scaling variance}}$$

As it can be seen, in order to obtain the BE limit, there are three quantities that need to be specified. They are (i) average BE limit, (ii) variance terms offset, and (iii) scaling variance, respectively. The 1999 FDA guidance indicates that the final specification of those parameters should be based on the results of the ongoing simulation study. However, the following values are recommended in the FDA's draft guidance.

As a result of the low variability of *in vitro* measurements, at the present time, the FDA recommends that the ratio of geometric means should fall within 0.90 and 1.11. As a result, a value of 0.90 is recommended as the average BE limit for *in vitro* data.

The objective of variance terms offset is to allow some difference among the total variances that may be inconsequential. As a result of the low variability of *in vitro*

measurements, the FDA recommends that a value of 0 should be taken based on the guidance of population and individual bioequivalence.^[4] In practice, however, a value of 0.01 may be accepted by the FDA for variance terms offset depending upon the nature of the drug products under investigation.

The purpose of scaling variance is to adjust the BE criterion depending on the reference product variance. When the reference variance is greater than the scaling variances, the limit is widened. On the other hand, the limit is narrowed when reference variance is less than scaling variance. The FDA indicates that the choice of the scaling variance should be at least 0.1.

As a result, the specification of 0.90 for the average BE limit—0.0 for the variance offset and 0.10 for scaling standard deviation—gives the following BE limit:

$$\theta_{BE} = \frac{\log(0.9)^2 + 0}{0.1^2} = 1.11$$

Nonprofile Analysis

The FDA^[3] indicates that the *in vitro* bioequivalence of nasal aerosols and sprays can be established by seven bioequivalence tests. They are classified as either the nonprofile analysis or the profile analysis. Nonprofile analysis applies to emitted dose or spray content uniformity, through container life, droplet size distribution, spray pattern, and priming/repriming. The criterion for nonprofile *in vitro* bioequivalence is described as follows.

Let y_T , y_R , and y'_R be independent *in vitro* bioavailabilities, where y_T is from the test product and y_R and y'_R are from the reference product. The two products are said to be *in vitro* bioequivalent if $\theta < \theta_{BE}$, where:

$$\theta = \frac{E(y_R - y_T)^2 - E(y_R - y'_R)^2}{\max\{\sigma_0^2, E(y_R - y'_R)^2/2\}} \quad (1)$$

θ_{BE} a prespecified BE limit and σ_0^2 is a prespecified constant. Values of σ_0^2 and θ_{BE} can be found in the FDA guidance. According to the FDA guidance, *in vitro* bioequivalence can be claimed if the hypothesis that $\theta \geq \theta_{BE}$ is rejected at the 5% level of significance, provided that the ratio of geometric means between drug products is within 0.90 and 1.11.

Let m_T and m_R be the number of canisters from the test product and the reference product, respectively, and one observation from each sample (e.g., bottle or canister) is obtained. The data can be described by the following model:

$$y_{jk} = \mu_k + \varepsilon_{jk}, \quad j = 1, \dots, m_k \quad (2)$$

where $k = T$ for the test product, $k = R$ for the reference product, μ_T and μ_R are fixed product effects, ε_{jk} 's are

independent random measurement errors distributed as $N(0, \sigma_k^2)$, $k = T, R$. Under model 2, the parameter θ in Eq. 1 is equal to:

$$\theta = \frac{(\mu_T - \mu_R)^2 + \sigma_T^2 - \sigma_R^2}{\max\{\sigma_0^2, \sigma_R^2\}} \quad (3)$$

As a result, $\theta < \theta_{BE}$ is equivalent to where ζ is the linearized BE parameter given by:

$$\zeta = (\mu_T - \mu_R)^2 + \sigma_T^2 - \sigma_R^2 - \theta_{BE} \max\{\sigma_0^2, \sigma_R^2\} \quad (4)$$

The bioequivalence can be concluded by constructing an approximate 95% upper bound for ζ . If the 95% upper bound is less than 0, *in vitro* bioequivalence is established, or otherwise rejected. In order to obtain the approximate 95% upper bound, the FDA^[2,3] recommends the following procedure proposed by Hyslop et al.,^[5] which was originally developed for the establishment of *in vivo* individual bioequivalence under a 2×4 crossover design. Let ζ_U denote the 95% upper bound for ζ and:

$$\begin{aligned} \hat{\delta} &= \bar{y}_T - \bar{y}_R \\ s_k^2 &= \frac{1}{m_k - 1} \sum_{j=1}^{m_k} (y_{jk} - \bar{y}_k)^2 \\ \bar{y}_k &= \frac{1}{m_k} \sum_{j=1}^{m_k} y_{jk} \end{aligned}$$

Then, it follows that:

$$\tilde{\zeta}_U = \hat{\delta}^2 + s_R^2 - s_T^2 \theta_{BE} \max\{\sigma_0^2, s_R^2\} + \sqrt{U}$$

where U is the sum of the following three quantities:

$$\begin{aligned} &\left[\left(|\hat{\delta}| + z_{0.95} \sqrt{\frac{S_T^2}{m_T} + \frac{S_R^2}{m_R}} \right)^2 - \hat{\delta}^2 \right] \\ &S_T^4 \left(\frac{m_T - 1}{\chi_{0.05; m_T - 1}^2} - 1 \right)^2 \end{aligned}$$

and

$$(1 + c\theta_{BE})^2 S_R^4 \left(\frac{m_R - 1}{\chi_{0.95; m_R - 1}^2} - 1 \right)^2$$

where $c = 1$ if $S_R^2 \geq \sigma_0^2$, $c = 0$ if $S_R^2 < \sigma_0^2$, z_a is the a th quantile of the standard normal distribution, and $\chi_{r,a}^2$ is the a th quantile of the central chi-square distribution with r degrees of freedom. As suggested by the FDA, *in vitro* bioequivalence can be claimed if $\tilde{\zeta}_U < 0$. This procedure is recommended by the FDA guidance.

Profile Analysis

As indicated in the FDA^[2] profile analysis using a confidence interval approach should be applied to cascade impactor (CI) or multistage liquid impinger (MSLI) for particle size distribution. As indicated in the 1999 FDA guidance, equivalence may be assessed based on chi-square differences. The idea is to compare the profile difference between test product and reference product samples to the profile valuation between reference product samples. More specifically, let y_{ijk} denote the observation from the j th subject's i th stage in the k th treatment. Given a sample (j_0) from test product and two samples (j_1, j_2) from reference products and assuming that there are a total of S stages, the profile distance between test and reference is given by:

$$d_{TR} = \sum_{i=1}^S \frac{(y_{ij0T} - 0.5(y_{ij1R} + y_{ij2R}))^2}{(y_{ij0T} - 0.5(y_{ij1R} + y_{ij2R}))^2}$$

Similarly, the profile variability within reference is defined to be:

$$d_{RR} = \sum_{i=1}^S \frac{(y_{ij1R} - y_{ij2R})^2}{0.5(y_{ij1R} + y_{ij2R})}$$

For a given triplet sample of (Test, Ref. [1], Ref. [2]), the ratio of d_{TR} and d_{RR} (i.e., $rd = d_{TR}/d_{RR}$) can then be used as a bioequivalence measure for the triplet samples between the two drug products. For a selected sample, the 95% upper confidence bound of $E(rd) - E(d_{TR}/d_{RR})$ is then used as a bioequivalence measure for the determination of bioequivalence. In other words, if the 95% upper confidence bound is less than the bioequivalence limit, then we claim that the two products are bioequivalent.

The FDA^[2] recommends a bootstrap procedure to construct the 95% upper bound for $E(rd)$. The procedure is described below. Assume that the samples are obtained in a two-stage sampling manner. In other words, for each treatment (test or reference), three lots are randomly sampled. Within each lot, 10 samples (e.g., bottles and canisters) are sampled. The following paragraph is quoted from the 1999 FDA guidance regarding the bootstrap procedure to establish profile bioequivalence.

For an experiment consisting of three lots each of test and reference products, and with 10 canisters per lot, the lots can be matched into six different combinations of triplets with two different reference lots in each triplet. The 10 canisters of a test lot can be paired with the 10 canisters of each of the two reference lots in $(10 \text{ factorial})^2 = (3,628,800)^2$ combinations in each of the lot triplets. Hence a random sample of the N canister pairing of the six Test–Ref. [1]–Ref. [2] lot triplets is needed. rd is estimated by the sample mean of the rd s calculated for the triplets in 10 selected samples of N .

In the sample guidance, the FDA recommends that a value of 500 should be taken for N .

RECENT DEVELOPMENT

Nonprofile Analysis

As indicated earlier, the FDA^[2] requires at least 30 samples to be taken from each of the test and the reference drug products (i.e., $m_k = 30$). However, $m_k = 30$ may not be enough to achieve a desired power for the bioequivalence test. In practice, there are two options to increase the power. One is to increase the sample size and the other one is to increase the replicates per sample. Increasing the sample size can certainly increase the power, but in some situations, obtaining replicates from each bottle or canister may be more practical and/or cost-effective. However, how to perform the statistical analysis based on replicates becomes a problem of interest.

Chow et al.^[6] proposed the following method to assess *in vitro* bioequivalence when a replicate from each bottle or canister is available. Suppose that there are n_k replicates from each bottle or canister for product k . Let y_{ijk} be the i th replicate in the j th canister under product k . Let b_{jk} be the between-bottle or between-canister variation and let e_{ijk} be the within-bottle or within-canister measurement error. Then:

$$y_{ijk} = \mu_k + b_{jk} + e_{ijk}, \quad i = 1, \dots, n_k, \quad j = 1, \dots, m_k \quad (5)$$

where b_{jk} 's and e_{ijk} 's are independent, $b_{jk} \sim N(0, \sigma_{Bk}^2)$, and $e_{ijk} \sim N(0, \sigma_{Wk}^2)$. Under model 5, the total variances σ_T^2 and σ_R^2 in Eqs. 3 and 4 are equal to $\sigma_{BT}^2 + \sigma_{WT}^2$ and $\sigma_{BR}^2 + \sigma_{WR}^2$, respectively (i.e., the sums of between-bottle or between-canister and within-bottle or within-canister variances). The parameter θ in Eq. 1 is still given by Eq. 3 and $\theta < \theta_{BE}$ if and only if $\zeta < 0$, where ζ is given in Eq. 4.

Under model 5, an approximate 95% upper bound for ζ is given by:

$$\hat{\zeta}_U = \hat{\delta}^2 + s_{BT}^2 + (1 - n_T^{-1})s_{WT}^2 - s_{BR}^2 - (1 - n_R^{-1})s_{WR}^2 - \theta_{BE} \max\{\sigma_0^2, s_{BR}^2 + (1 - n_R^{-1})s_{WR}^2\} + \sqrt{U}$$

where U is the sum of the following five quantities:

$$\left[\left(|\hat{\delta}| + z_{0.95} \sqrt{\frac{s_{BT}^2}{m_T} + \frac{s_{BR}^2}{m_R}} \right)^2 - \hat{\delta}^2 \right] s_{BT}^4 \left(\frac{m_T - 1}{\chi_{0.05; m_T - 1}^2} - 1 \right)^2$$

$$(1 - n_T^{-1})^2 s_{WT}^4 \left(\frac{m_T(n_T - 1)}{\chi_{0.05; m_T(n_T - 1)}^2} - 1 \right)^2$$

$$(1 + \theta_{BE})^2 s_{BR}^4 \left(\frac{m_R - 1}{\chi_{0.95; m_R - 1}^2} - 1 \right)^2$$

and

$$(1 + c\theta_{BE})^2 (1 - n_R^{-1})^2 s_{WR}^4 \left(\frac{m_R(n_R - 1)}{\chi_{0.95; m_R(n_R - 1)}^2} - 1 \right)^2$$

and $c = 1$ if $s_{BR}^2 + (1 - n_R^{-1})s_{WR}^2 \geq \sigma_0^2$ and $c = 0$ if $s_{BR}^2 + (1 - n_R^{-1})s_{WR}^2 < \sigma_0^2$. *In vitro* bioequivalence can be claimed if $\hat{\zeta}_U < 0$.

If the difference between model 2 and model 5 is ignored and the confidence bound $\hat{\zeta}_U$ with m_k replaced by $m_k n_k$ (instead of $\hat{\zeta}_U$) is used, then the asymptotic size of the test procedure is not 5%.

Profile Analysis

The bootstrap procedure described in the section “Bioequivalence Limit” has received much attention and criticism since it was introduced by the FDA. The major criticisms are described below.

First, the statistical properties of this procedure are unknown. It includes two aspects. One is that the statistical model, which should be used to describe the profile data, is not clearly defined in the FDA guidance. In addition, even under an appropriate statistical model, the statistical properties of the bootstrap procedure are still unknown. More specifically, is the bootstrap sample mean a consistent estimator for $E(rd)$? Is the 95% percentile of the bootstrap samples an appropriate 95% upper bound for $E(rd)$? These questions are not addressed in the FDA guidance.

Second, no criteria are given regarding the passage or failure of the bioequivalence study. This is the issue that confuses most researchers/scientists in practice. After the conduction of a valid trial and an appropriate statistical analysis following the FDA guidance, the sponsor still cannot tell if its product has passed or failed the bioequivalence test. This is a direct consequence of our first point (i.e., the statistical properties of the recommended bootstrap procedure are unknown).

Third, the simulation study using different random number generation schemes may produce contradictory results. It is possible for a good product to fail the bioequivalence test simply because of “bad luck.” It is also possible for a bad product to pass the bioequivalence test with an “appropriate” choice of random number generation scheme. As a result, researchers/scientists tends to reply

more on the descriptive statistics of the two drug products (treatment and reference) in order to assess their bioequivalence instead of the bootstrap procedure. The proposed bootstrap procedure recommended by FDA is not as reliable as it should be.

As a result, further research of profile analysis becomes a problem of interest in practice. More specifically, the questions of interest include: (i) What statistical model should be used to describe the profile data? (ii) Is $E(rd)$ defined by the FDA as a good parameter for characterizing the bioequivalence between test and reference products? Can we define the test-to-reference distance and reference-to-reference variability differently? (iii) What BE limit should be used? (iv) What statistical procedure should we use to evaluate the *in vitro* bioequivalence between the two products based on appropriate model, parameter, and bioequivalence criterion?

Sample Size

The FDA^[2,3] indicates that an *in vitro* bioequivalence study should be based on testing a suitable number of bottle or canisters from each of three batches (lots) of the test and reference drug products. The number of bottles (canisters) to be studied for each batch (lot) should be no less than 10. As a result, a minimum of 30 samples is required for each of the test and the reference drug products.

However, the FDA's requirement may not yield sufficient power for the establishment of *in vitro* bioequivalence between drug products. Chow et al.^[6] propose a procedure for determining sample sizes as follows.

In practice, it is commonly preferred to choose $m = m_T = m_R$ and $n = n_T = n_R$ so that the power of the bioequivalence test reaches a given level β (say 80%) when the unknown parameter vector $\psi = (\delta, \sigma_{BT}^2, \sigma_{BR}^2, \sigma_{WT}^2, \sigma_{WR}^2)$ is set at some initial guessing value ψ for which the value of ζ (denoted by $\hat{\zeta}$) is negative. Let U be given in the definition of $\hat{\zeta}_U$ and let $U\beta$ be the same as U but with 5% and 95% replaced by $1 - \beta$ and β , respectively. Because:

$$P(\hat{\zeta}_U < \zeta + \sqrt{U} + \sqrt{U\beta}) \approx \beta$$

the power of the bioequivalence test $P(\hat{\zeta}_U < 0)$ is approximately larger than β if $\zeta + \sqrt{U} + \sqrt{U\beta} \leq 0$. Let $\bar{U}$ and $\tilde{U}_\beta$ be U and $U\beta$, respectively, with $(\delta, s_{BT}^2, s_{BR}^2, s_{WT}^2, s_{WR}^2)$ replaced by. Then, the sample sizes $m = m_T = m_R$ and $n = n_T = n_R$ that produce a test with a power of approximately β should satisfy:

$$\bar{\zeta} + \sqrt{\bar{U}} + \sqrt{\tilde{U}_\beta} \leq 0 \quad (6)$$

As a result, having a large m and a small n is an advantage when mn , the total number of observations for one

treatment, is fixed. Thus the optimal sample size and the replicates combination can be determined by the following procedure:

- Step 1. Set $m = 30$ and $n = 1$. If Eq. 6 holds, stop, and the required sample sizes are $m = 30$ and $n = 1$; otherwise, go to Step 2.
- Step 2. Let $n = 1$ and find a smallest integer m^* such that Eq. 6 holds. If $m^* \leq m_+$ (the largest possible number of canisters in a given problem), stop, and the required sample sizes are $m = m^*$ and $n = 1$; otherwise, go to Step 3.
- Step 3. Let $m = m_+$ and find a smallest integer n^* such that Eq. 6 holds. The required sample sizes are $m = m_+$ and $n = n^*$.

If in practice it is much easier and inexpensive to obtain more replicates than to sample more canisters, then Steps 2–3 in the previous procedure can be replaced by:

- Step 2'. Let $m = 30$ and find a smallest integer n^* such that Eq. 6 holds. The required sample sizes are $m = 30$ and $n = n^*$.

Because selecting sample sizes according to Eq. 6 only produces a test with approximate power β , we conduct a simulation study to examine the actual power corresponding to the selected sample sizes according to Steps 1–3 (or Steps 1 and 2'). That is, for a given combination of parameter values in Table 1, we select sample sizes m^* and n^* according to Steps 1–3 or Steps 1 and 2' with $\beta = 80\%$, and then compute the actual power p corresponding to the selected m^* and n^* by 10,000 simulations. Note that m_+ is set to be ∞ in the simulation so that Step 3 is not needed.

The performance of the above sample size determination procedure is evaluated by simulation. Table 1 shows the selected sample sizes for a nominal power of 80%, as reported by Chow et al.^[6] The results show that the selected sample sizes produce a test with power $\geq 75\%$, except for two cases where the power is about 73%.

CONCLUSION

For the assessment of *in vitro* bioequivalence, the FDA^[2,3] requires that *in vitro* testing of emitted dose uniformity, droplet size distribution, spray pattern, plume geometry, and priming and re-priming be done to demonstrate comparable delivery characteristics between two drug products. Those tests can be divided into two categories. They are, namely, profile and nonprofile analysis. For profile analysis, a statistical procedure similar to the one for testing individual bioequivalence^[5] are adopted. However, for profile analysis, no satisfactory statistical procedure is available for establishment of *in vitro* bioequivalence. Further study is needed.

In Vitro Testing: Dissolution Profile Comparison

Yi Tsong, Pradeep M. Sathe, and Vinod P. Shah

U.S. Food and Drug Administration, Rockville, Maryland, U.S.A.

Abstract

Dissolution test is one of the most valuable in vitro tests used to assure drug product quality. This entry offers theoretical considerations, various approaches, and similarity criterion to aide in the comparison of dissolution profiles.

INTRODUCTION

Dissolution test is one of the most important in vitro tests that is used to assure the drug product quality. A dissolution profile comparison and assurance of similar profile is also an important step in assuring product performance in the presence of a change and in providing biowaivers for lower strength of products from a given manufacturer.

For the assessment of postapproval changes in a drug product such as (1) scale-up, (2) manufacturing site, (3) component and composition, and (4) equipment and process changes, a comparison of dissolution profiles between prechange and postchange products was first recommended in the SUPAC-IR guidance.^[1] This provided a measure of product similarity using dissolution profile characteristics. Later this was also recommended in the other Food and Drug Administration (FDA) Guidances.^[2–4] Changes approved based on a meaningful dissolution data are often accepted as adequate to assure appropriate release and therefore desired in vivo performance. In addition, dissolution profile similarity is also used to provide biowaivers of lower strength of immediate- and modified-release dosage forms as long as the higher strength meets the bioequivalence requirements and the lower strengths show formulation proportionality to the highest strength, and employ the same release mechanism in the case of modified-release dosage forms.^[5]

Dissolution profiles may be considered similar by virtue of 1) overall (or global) profile similarity and 2) uniform similarity at every dissolution sample point.

MEASURES OF DIFFERENCE OR SIMILARITY BETWEEN TWO DISSOLUTION PROFILES

In dissolution profile comparison, the dissolution measurements of both the test and reference batches should be

made under identical conditions and the dissolution sample points for both profiles should be the same, e.g., for immediate release products, 15, 30, 45, and 60 min and for controlled-release products, 1, 3, 5, and 8 hr. Let

μ_{ti}, μ_{ri} = the population percent dissolutions measured at t_i , the i th ($i = 1, \dots, P$) time point of the test and reference products, respectively, with $t_0, \mu_{r(0)}, \mu_{r(0)} = 0$
 $D_i = |\mu_{ti} - \mu_{ri}|$

Several measures of the difference or similarity of two profiles were proposed in the last decade.^[6]

1. Maximum distance

$$D_{\text{Max}} = \text{Max}_{i=1 \text{ to } P} D_i$$

2. Difference of area under the profiles

$$D_{\text{AUC}} = \sum_{i=1}^P [(\mu_{ti} + \mu_{t(i-1)}) - (\mu_{ri} + \mu_{r(i-1)})](t_i - t_{i-1})/2$$

D_{Max} is defined as a measure of the maximum difference of two curves and it is a measure of uniform similarity. D_{AUC} , on the other hand, is an insensitive global measure of the difference between the two mean dissolution profiles (by ignoring the difference between the two mean profiles) at individual time points. Other measurements defined as functions of the difference at each time point are either derived or modified from the following two basic metrics of difference between two mean dissolution curves.

3. Mean distance

$$D^1 = \sum_{i=1}^P |\mu_{ti} - \mu_{ri}|/P$$

The views expressed in this article are those of the authors and do not represent the official position of the U.S. Food and Drug Administration.

A generalized form of the mean distance can be written as

$$D^1 = \sum_{i=1}^P w_i |\mu_{ti} - \mu_{ri}| / P$$

where w_i is the weight for $|\mu_{ti} - \mu_{ri}|$.

The following three measures are modifications of D^1 with different weights.

(3.1) Area between the profiles

$$D_{ABC} = \sum_{i=1}^{p-1} |\mu_{ti} - \mu_{ri}| \left[(t_{i+1} + t_i)/2 - (t_i + t_{i-1})/2 \right]$$

which uses $w_i = [(t_{i+1} + t_i)/2 - (t_i + t_{i-1})/2]P$.

D_{ABC} is insensitive if the point of cross of the two dissolution profiles cannot be identified.

(3.2) Difference factor f_1

$$f_1 = \left\{ \left[\sum_{i=1}^P |\mu_{ti} - \mu_{ri}| \right] / \left[\sum_{i=1}^P \mu_{ri} \right] \right\} \times 100$$

proposed by Moore and Flanner^[7] can be considered as a weighted D_1 with $w_i = 100P/(\sum_{i=1}^P \mu_{ri})$. The difference factor f_1 is a ratio of the absolute difference of the test and reference normalized with respect to the sum of the mean percent dissolutions of the reference lot. This measure is therefore a scaled difference of the two profiles. Because it is normalized with respect to the reference means, the measure is sensitive to the reference product dissolution profile. In other words, with exactly the same size of difference between two profiles, the measure can give different values when the reference profiles are different.

(3.3) First-order Rescigno index

$$D_{R(1)} = \left\{ \left[\sum_{i=1}^P |\mu_{ti} - \mu_{ri}| \right] / \left[\sum_{i=1}^P (\mu_{ti} + \mu_{ri}) \right] \right\}$$

The measure originally proposed by Rescigno^[8] was in general form. The first- and second-order indices are more frequently referenced in the literature. This measure suffers the similar sensitivity as f_1 by normalizing D_1 with respect to $[\sum_{i=1}^P (\mu_{ti} + \mu_{ri})]/P$, the mean of the sum of the two dissolution values.

4. Mean squared distance

$$D^2 = \left[\sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 / P \right]^{1/2}$$

A few other measures take the general form of a mean squared difference. These are represented as follows:

$$D^{2*} = \left[\sum_{i=1}^P w_i (\mu_{ti} - \mu_{ri})^2 / P \right]^{0.5}$$

where w_i is the weight for $(\mu_{ti} - \mu_{ri})^2$.

With squared terms, these measures are more sensitive to large differences at any time point compared to the measures that use absolute value terms. The second-order Rescigno index and the f_2 measures are two examples of this class.

(4.1) Second-order Rescigno Index^[8]

$$D_{R(2)} = \left\{ \left[\sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 \right] / \left[\sum_{i=1}^P (\mu_{ti} + \mu_{ri})^2 \right] \right\}^{0.5}$$

uses $w_i = P/[\sum_{i=1}^P (\mu_{ti} + \mu_{ri})^2]$.

$D_{R(2)}$ has the same sensitivity problem as the first-degree Rescigno index.

(4.2) Similarity factor f_2 ^[7]

$$f_2 = 50 \log \left\{ \left[1 + (1/P) \sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 \right]^{-0.5} \times 100 \right\}$$

As a function of $[1 + (1/P) \sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2]^{-0.5}$, f_2 increases as $\sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2$ decreases. In contrast to D_2 , through mathematical transformation, f_2 measures the similarity of the two profiles. In practice, the measures defined in (1) to (4.2) are estimated by substituting $\bar{x}_{ti}$ and $\bar{x}_{ri}$, the sample means, for μ_{ti} and μ_{ri} , respectively, in the formulae. These estimates are not normalized by the covariance or variance of percent dissolution and do not have a known sampling distribution or asymptotic sampling distribution.

A traditional measure of the difference with covariance normalization may be given (in the multivariate form) as follows.

5. Standardized mean squared distance (or Mahalanobis distance)^[9]

$$D_M = \sqrt{[(\mu_t - \mu_r)' \Sigma_{\text{pooled}}^{-1} (\mu_t - \mu_r)] n/2}$$

where $\Sigma_{\text{pooled}} = (\Sigma_t + \Sigma_r)/2$ is the covariance matrix pooled across both batches, $\mu_t = (\mu_{t1}, \mu_{t2}, \dots, \mu_{tP})$ is the vector of the mean dissolution of the test batch, μ is defined the same way, and Σ_t and Σ_r are the covariance matrices of test and reference batches, respectively.

Note that the dissolution curves of different products are most discriminative at the time points at which dissolution rate accelerates. By assigning weight to the dissolution difference at the sample time when the dissolution is almost complete, the measures may become insensitive to the difference between two dissolution curves. Hence, selecting the weight needs to be carefully considered with respect to the selection of sample points.

SELECTION OF MEASURES

For regulatory considerations, the FDA CDER Immediate Release Drug Dissolution Profile Comparison Working Group evaluated all potential measures and determined to limit further evaluation to mean squared distances D^2 , similarity factor f_2 , and standardized mean squared distance D_M . The maximum distance measure was not considered due to its oversensitivity to failing any similarity requirement based on a single large distance at any sample point. On the other hand, mean distance, difference between the area between profiles, and area between profiles are not sensitive enough to detect large dissolution difference at a particular sample point. Both Rescigno indices and the difference factor f_1 were not considered because they are denominator sensitive. The statistical properties of similarity factor f_2 and standardized mean squared distance D_M will be discussed in the following sections.

DISSOLUTION PROFILE SIMILARITY TESTING BASED ON D_M

D_M is estimated by substituting x_t , x_r , the sample means and S_{pooled} , S_t , S_r for the corresponding parameters in the formula. With the assumption of equal variance–covariance matrices and multivariate normal assumption of x_t and x_r , the statistical properties of the estimate of D_M were well studied in the literature of statistical multivariate analysis.^[10,11] The multivariate confidence region has often been used to describe the variation of estimation of D_M . The decisions of similarity can be made with appropriate comparison of the confidence limits of the metric with a prespecified similarity limit ΔD_M . The 90% confidence limits of D_M can be obtained from the multivariate confidence region of the expected values of x_t and x_r , under multivariate normal assumption.

The $(1 - \alpha)100\%$ confidence region of all differences, y , satisfies the following equation,

$$T^2 = K(y - (x_t - x_r))' S_{\text{pooled}}^{-1} (y - (x_t - x_r)) \leq F_{P, 2n-P-1, 90}$$

where $K = [n^2/(2n)](2n - P - 1)/[(2n - 2)P]$, $F_{P, 2n-P-1, 90}$ is the 90th percentile of F distribution with degrees of freedom $(P, 2n - P - 1)$. It is obvious that this requires $2n$ to be greater than $P + 1$.

The $(1 - \alpha)100\%$ confidence interval (D_M^l , D_M^u) of D_M is obtained using the Lagrange multiplier method^[10] such that

$$D_M^u = \text{Max} \left(\sqrt{y_1^{*'} S_{\text{pooled}}^{-1} y_1^{*} n/2}, \sqrt{y_2^{*'} S_{\text{pooled}}^{-1} y_2^{*} n/2} \right)$$

$$D_M^l = \text{Min} \left(\sqrt{y_1^{*'} S_{\text{pooled}}^{-1} y_1^{*} n/2}, \sqrt{y_2^{*'} S_{\text{pooled}}^{-1} y_2^{*} n/2} \right)$$

where

$$y_1^{*} = (x_t - x_r) \left(1 + \sqrt{F_{P, 2n-P-1, 90} / [K(x_t - x_r)' S_{\text{pooled}}^{-1} (x_t - x_r)]} \right)$$

$$y_2^{*} = (x_t - x_r) \left(1 - \sqrt{F_{P, 2n-P-1, 90} / [K(x_t - x_r)' S_{\text{pooled}}^{-1} (x_t - x_r)]} \right)$$

Dissolution profile similarity is concluded if $D_M^u < \Delta D_M$.

DISSOLUTION PROFILE SIMILARITY TEST BASED ON SIMILARITY FACTOR f_2

Moore and Flanner^[7] proposed the similarity factor f_2 to measure the similarity between two expected dissolution profiles. The simplicity of the similarity factor generated considerable interest and was therefore recommended for dissolution profile comparison in the FDA's Guidance for Industry.^[1-5] Subsequently, many examples of the application of f_2 were published in the literature.^[12,13] These applications were often carried out using point estimate by simply substituting $\bar{x}_{ti}$ and $\bar{x}_{ri}$ for μ_{ti} and μ_{ri} without considering data variation. Most of the criticisms^[14-16] on the use of f_2 were made without realizing that f_2 represents the parameter and is not a statistical testing procedure itself. The statistical properties of f_2 and the similarity testing criteria based on f_2 were, however, delineated later.^[17,18]

Theoretical Considerations

To illustrate the applications of similarity factor f_2 , consider the dissolution profiles of the two batches generated using P number of sample points. Let $(\mu_{r1}, \mu_{r2}, \dots, \mu_{rP})$ represent the cumulative dissolution measures at P time points on the reference profile and $(\mu_{t1}, \mu_{t2}, \dots, \mu_{tP})$ be the corresponding P measures on the test profile. The distances between the two profiles at these P time points are $(|\mu_{r1} - \mu_{t1}|, |\mu_{r2} - \mu_{t2}|, \dots, |\mu_{rP} - \mu_{tP}|)$. The distances at the P time points may be combined into one measure, $D^2 = \sqrt{\{\sum_{i=1}^P [(\mu_{r1} - \mu_{t1})^2 + (\mu_{r2} - \mu_{t2})^2 + \dots + (\mu_{rP} - \mu_{tP})^2]\}}$, which is the square root of the sum of squared differences.

$$f_2 = 50 \log \left\{ \left[1 + (1/P) \sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 \right]^{-1/2} \times 100 \right\} \\ = 50 \log \{ [1 + (D^2)^2]^{-1/2} \times 100 \}$$

where log is the logarithm based on 10.

If Δf_2 is a required similarity limit for f_2 , then the two dissolution profiles are similar if $f_2 > \Delta f_2$.

Estimation and Confidence Interval of Similarity Factor

Let $(\bar{x}_{r1}, \bar{x}_{r2}, \dots, \bar{x}_{rP})$ and $(\bar{x}_{t1}, \bar{x}_{t2}, \dots, \bar{x}_{tP})$ be the sample mean of n ($= 12$ generally) tablets measured at the P time points of reference and test products, respectively. With these sample means, f_2 is estimated as follows

$$\hat{f}_2 = 50 \log \left\{ \left[1 + (1/P) \sum_{i=1}^P (\bar{x}_{ti} - \bar{x}_{ri})^2 \right]^{-1/2} \times 100 \right\}$$

Assuming that the expected value of $\hat{f}_2$ equals f_2 , i.e., $E(\hat{f}_2) = f_2$, for an assurance of 95% correct decision, similarity of the two profiles can be concluded if the lower limit of the 90% confidence interval of $E(\hat{f}_2) > \Delta f_2$. Both the exact and the asymptotic distribution of $\hat{f}_2$ are complicated to derive. Alternately, the 90% confidence interval can be simulated through the bootstrap method^[19] as given by Shah et al.^[17] and Ma et al.^[18] To make the method easy to use by nonstatisticians, Shah et al. proposed to use $\hat{f}_2$ only when the data variation is small (i.e., with CV < 10% at any point).

Bias of the Estimate of Similarity Factor

Assuming that there are n tablets in both the test and reference batches, consider the expected value of $[(1/P) \sum_{i=1}^P (\bar{x}_{ti} - \bar{x}_{ri})^2]$,

$$\begin{aligned} E \left[(1/P) \sum_{i=1}^P (\bar{x}_{ti} - \bar{x}_{ri})^2 \right] \\ = E \left[(1/P) \left\{ \sum_{i=1}^P [(\bar{x}_{ti} - \bar{x}_{ri}) - (\mu_{ti} - \mu_{ri})]^2 + \sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 \right\} \right] \\ = (1/P) \left[\sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 + \sum_{i=1}^P (\sigma_{ti}^2 + \sigma_{ri}^2)/n \right] \end{aligned}$$

where σ_{ti}^2 and σ_{ri}^2 are the variances of percent dissolution measured at the i th time point of the test and reference batches, respectively.

When n becomes large, the expected value of the mean squared differences between sample means $E[(1/P) \sum_{i=1}^P (\bar{x}_{ti} - \bar{x}_{ri})^2]$ becomes very close to $(1/P) [\sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2]$, the mean squared difference between population means. Hence, $\hat{f}_2$ is an asymptotically unbiased estimator of f_2 .

On the other hand,

$$\begin{aligned} E(\hat{f}_2) &= E \left\{ 50 \log \left[\left(1 + (1/P) \sum_{i=1}^P (\bar{x}_{ti} - \bar{x}_{ri})^2 \right)^{-1/2} \times 100 \right] \right\} \\ &= E \left\{ 100 - 25 \log \left[1 + (1/P) \sum_{i=1}^P (\bar{x}_{ti} - \bar{x}_{ri})^2 \right] \right\} \\ &\approx 100 - 25 \log \left\{ 1 + E \left[(1/P) \sum_{i=1}^P (\bar{x}_{ti} - \bar{x}_{ri})^2 \right] \right\} \\ &= 100 - 25 \log \left\{ 1 + (1/P) \left[\sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 + \sum_{i=1}^P (\sigma_{ti}^2 + \sigma_{ri}^2)/n \right] \right\} \end{aligned}$$

which is

$$\begin{aligned} &< 100 - 25 \log \left\{ 1 + (1/P) \sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 \right\} \\ &= 50 \log \left\{ \left[1 + (1/P) \sum_{i=1}^P (\mu_{ti} - \mu_{ri})^2 \right]^{-1/2} \times 100 \right\} \\ &= f_2 \end{aligned}$$

This implies that the $\hat{f}_2$ is a conservative estimate of f_2 . This conservative bias makes the use of $\hat{f}_2$ without taking into consideration the variance when the variance is small. The bias was more thoroughly studied and discussed based on simulation results by Ma et al.^[18]

SIMILARITY CRITERION

It is clear that one of the criteria for similarity test is that the dissolution profiles of the prechange batches should be responsible. The similarity limit or region is determined as the tolerable difference in the dissolution profile between two batches of the prechange product. Ideally, such a limit or region is determined empirically, e.g., using the confidence limits of the 99% or 95% confidence interval of individual dissolution profile difference (in terms of the metric to be used) between any two prechange batches. However, often the similarity limit is based on chemist's experience. For example, two profiles can be determined as similar if the average difference at all time points is no more than a given percentage, say, 10% or 15%. The proposed similarity limits of average of 10% difference across all time points was based on an unofficial survey carried out by the FDA Dissolution Profile Comparison Working Group. The simple limit was selected with the objection to select a measure that is reasonably sensitive to a single

large difference. The similarity limit is then transformed to the corresponding value of the measures. For example, with 10% average difference at all time points, the similarity limits for the corresponding difference or similarity measures are

$$\Delta f_2 = 50 \log \left\{ \left[1 + (1/P) \sum_{i=1}^P (10)^2 \right]^{-0.5} \times 100 \right\} = 49.89 \approx 50$$

$$\Delta D_M = \sqrt{[(10)' \Delta_{\text{pooled}}^{-1} (10)]} \approx \sqrt{[(10)' S_{\text{pooled}}^{-1} (10)]}$$

where Δ_{pooled} is the pooled covariance/ $\sqrt{n}$.

Note that both measures are sensitive to the selections of time points. For example, at the time point when the dissolution is not taking place or near saturated, the difference between two profiles is small. Measuring dissolution at such time points will make D_M small and f_2 large. In addition, the parametric confidence region based on D_M is limited to $2n - P - 1 > 0$. The number of time points is therefore limited.

MODELING APPROACH

The dissolution profile is often studied by fitting some empirical physicochemical model to mathematically describe the course of dissolution of a product.^[20–23] for immediate-release drug products, the following sigmoid curves were often found to fit the dissolution data well.

1. Exponential model

$$x(t) = x_{\text{max}} (1 - e^{-at})$$

where x_{max} is the maximum dissolvable quantity.

2. Probit model

$$x(t) = x_{\text{max}} A \Phi(\alpha + \beta A \log(t))$$

where $\Phi(y)$ is the standard normal variable.

3. Gompertz model

$$x(t) = x_{\text{max}} \exp[-\alpha e^{-\beta \log(t)}]$$

4. Logistic curve

$$x(t) = x_{\text{max}} A e^{(\alpha + \beta \log(t))} / \{1 + e^{(\alpha + \beta \log(t))}\}$$

5. Weibull curves

$$x(t) = x_{\text{max}} \{1 - \exp[-\alpha t^\beta]\}$$

where $x(t)$ is percent dissolved at time t divided by 100 and x_{max} is the maximum dissolution.

The parameter x_{max} in the above models is often set to be 100 unless the data clearly indicate otherwise.

Because α in each model determines the dissolution or undissolved proportion at $t = 1$, it is often described as location or scale parameter, whereas because β in each model determines the dissolution rate per unit of time, it is often described as the acceleration or shape parameter. In practical application, when the product has a large lag time t_0 , t in the models needs to be replaced by $t - t_0$.

Sathe et al.^[24,25] proposed the model-dependent approach with the following steps:

1. Establish a mathematical model describing dissolution data using the prechange product. For each tablet sampled from the batch, obtain the parameter values by fitting the selected model to the data.
2. Using the model selected based on a good fitting of the prechange product, determine the parameters of each tablet of the postchange product
3. Find the difference in the means of the parameters of the two products. Compare the upper limit(s) of the 90% confidence intervals of the difference of the means with a prespecified similarity limit for determining similarity.

In comparison to either D_M or f_2 measures, the model-dependent approach is more robust with respect to the choice of sampling points when the number of time points are large. It is recommended for dissolution curves that are sampled at many time points. It is also applicable for data of postchange products collected at different time points. The difficult part of this approach is the determination of the similarity limits.

ALTERNATE APPROACHES

Other than the above three measures recommended in the FDA Guidance, many statistical procedures or measures were proposed in the last decade.^[26–30] Ma et al.^[18,26] thoroughly studied the statistical properties of ΔD^1 (estimate of D^1 by substituting $(\bar{x}_{it}, -\bar{x}_{rt})$ for $(\mu_{it}, -\mu_{rt})$) and concluded that the exact or approximate distribution of the measure is difficult and complicated to derive. In addition, ΔD^1 is also a biased estimate of D^1 with the size of bias often smaller than when using f_2 for f_2 . However, the bias is minimal when the number of tablets is no less than 12. The advantage of using f_2 over D^1 is its ability to pick up the difference between the profiles. It can pick up any large difference between two profiles but it is not as sensitive as D_{max} .

Chow and Ki^[27] proposed a time series procedure to take into consideration the correlation among dissolution values at various time points and the correlation among the baskets used in testing. The procedure tests against a function of the Q value, which is the dissolution specification of the USP. As pointed out in the FDA Guidance, the

Q value is appropriate only for quality control and should not be used for dissolution profile comparison.

Gill^[29] proposed the application of split-plot trend analysis for dissolution profile comparison. The procedure is a hypothesis testing procedure such that by rejecting a null hypothesis of equal parameter one can conclude that the profiles are dissimilar. The concept of "concluding same by showing lack of power to reject a null hypothesis of sameness" has long been faulted in the statistical literature.

CONCLUSION

Dissolution test is one of the most valuable *in vitro* tests used to assure drug product quality. Similar dissolution profile assures product sameness and product performance in the presence of certain Scale-Up and Post Approval Changes. Several statistical approaches were studied by various authors for dissolution profile comparison. Similarity factor f_2 was found to be the simplest and most widely applicable method for this purpose, and is generally recommended for dissolution profile comparison in regulatory guidances. The statistical properties of f_2 and estimation of confidence interval have been delineated.

There is an average 10% difference across all time points in two dissolution profiles when substituted in the equation results in a f_2 value of ~50. f_2 value between 50–100 is considered to indicate product sameness and therefore similar product performance. Dissolution profile comparison is useful in providing biowaivers for lower strength of products from a given manufacturer, and also for *in vivo* studies based on the biopharmaceutics classification system.

In Vitro Testing: Micronucleus Test

Wherly P. Hoffman

Department of Biometrics, Elan Pharmaceuticals Inc., South San Francisco, California, U.S.A.

Michael L. Garriott (Retired), and Cindy Lee

Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

Abstract

Genetic toxicology tests are among the early studies conducted to assess the safety profile of a compound. One of the tests currently being examined is the *in vitro* micronucleus (IVM) test. This entry discusses the design, statistical analyses, and interpretation of results of the IVM test.

Keywords: Comparison test; *In vitro* micronucleus test; Trend test.

INTRODUCTION

Genetic toxicology tests are among the early studies conducted to assess the safety profile of a compound. They are designed to determine whether the compound can interact with DNA and lead to the production of gene mutations or chromosomal breakage. Some tests can also detect compounds that interact with components of the mitotic spindle apparatus. Although the tests required for registration of new pharmaceuticals are clearly defined, research investigating modifications to existing tests and development of new tests continues. One of the tests currently being examined is the *in vitro* micronucleus (IVM) test.^[1–4] The design, statistical analyses, and interpretation of results of the IVM will be discussed in this article. The section “Background” includes information pertaining to the relevance of the IVM to the toxicology safety profile. “Design” describes the statistical elements of the design for the test. “Statistical Analyses” discusses two statistical methods for analyzing data from the test. “Results—An Example” presents the results of an example, and “Conclusion” provides concluding remarks to summarize this article.

BACKGROUND

This section will briefly summarize why the IVM is being developed and how the test can be conducted. The procedure is described without great detail and is intended only to provide the reader with an understanding of how the data are obtained. This background will then lead into the subsequent sections on design and statistical methods.

Why the *In Vitro* Micronucleus Test

The rationale for the development of genetic toxicology tests and the reasons they are included in safety assessment are discussed in another chapter—“Ames Test.” Because different genetic toxicology tests measure different endpoints and because no single test is capable of detecting all of the various types of genetic damage that can occur, a battery of tests is conducted to assess safety. For pharmaceuticals, this battery generally consists of: (i) the Ames test, (ii) the *in vitro* chromosome aberration test, and (iii) the *in vivo* micronucleus test.^[5] The Ames test measures gene mutation in bacteria. The chromosome aberration test measures chromosomal damage in Chinese hamster ovary (CHO) cells, Chinese hamster lung (CHL) cells, or human lymphocytes (HL) grown in tissue culture. The micronucleus test is performed in mice or rats and assesses both chromosomal damage and interaction with the mitotic spindle apparatus, as micronuclei are either chromosomal fragments or whole chromosomes. Currently, an IVM test employing the same cells as the chromosome aberration test is often used very early in development as a screen for the more labor-intensive and more expensive chromosome aberration test. Additionally, this test is expected to become an acceptable alternative to the aberration test when submitting the compound for regulatory approval because of the similarity of qualitative results from the two tests.^[1,6,7] Therefore, it is important to consider statistical analyses of the data generated in conducting IVM.

In Vitro Micronucleus Test

As noted earlier, the IVM uses various immortal cell lines (CHO, CHL) or primary cell cultures of HL grown in various tissue culture mediums. There are several protocol

variations that have been examined by different laboratories, including the use of cytochalasin B and the need for an extended treatment in the absence of exogenous metabolic activation. Cytochalasin B blocks cell division and leads to an accumulation of binucleated cells.^[8,9] Micronuclei are then evaluated only in the binucleated cells to ensure that the cells divided following exposure to the test article. However, some researchers question the need for cytochalasin B when using immortal cell lines. An extended treatment in the absence of metabolic activation is used in the *in vitro* chromosome aberration assay to improve its utility for detecting spindle poisons; however, this aspect of the test is controversial and has led to an investigation of the need for this type of treatment in the IVM.^[4] An OECD guideline for the IVM is currently being developed with input from investigators who have evaluated the possible protocol variations and will ultimately determine the procedure to be used in the conduct of the test.^[10]

The procedure we used for the investigation of the IVM at Eli Lilly and Company was similar to that of Curry et al.^[11] and is briefly described as follows. CHO cells were seeded onto eight-well chamber slides 24 hours prior to dosing. Generally, each chemical was tested with eight concentrations that were equally spaced on a log scale, and each concentration was tested on two separate slides. These concentrations were determined from a preliminary cytotoxicity test. The highest concentration included was based on a general rule of 50% cell survival. Treatments were for 4 hours in the absence and in the presence of metabolic activation and for 24 hours in the absence of activation. Because micronuclei may occur spontaneously, a vehicle control slide was always included for each of the three treatments. One thousand (1000) binucleated cells per well were examined and the number of micronucleated, binucleated (MNBN) cells per 2,000 binucleated cells per concentration, including the vehicle control, was recorded. If a compound is not capable of causing chromosomal damage or interfering with the function of the mitotic spindle, then there should be no significant increase in the incidence of micronucleated cells compared to the number of micronucleated cells observed in the vehicle control.

Design

The number of micronuclei in 2,000 binucleated cells is the response to be statistically evaluated. It is the sum of two counts of 1,000 binucleated cells from each duplicate chamber on two separate slides. Three test conditions were included to ensure a thorough examination of each chemical tested: (i) a 4-hour exposure without metabolic activation, (ii) a 24-hour exposure without metabolic activation, and (iii) a 4-hour exposure with metabolic activation. The different exposure conditions were necessary because some chemicals are not directly mutagenic but are metabolized to chemicals that are mutagenic, while other chemicals may delay cell division. A control and up to eight concentration

levels are usually evaluated, and they are typically equally spaced on a log scale. For example, the evaluation of hydrogen peroxide under the third test condition included a control and eight concentration levels 0.16, 0.5, 1.6, 5, 16, 50, 160, and 320 µg/mL. As the survival of the cells will eventually decrease due to cytotoxicity as the concentration increases, it is important to have enough cells alive and available for the development of micronuclei for a proper evaluation of the compound effect. The concentrations should be high enough to allow induction of micronuclei, yet not so high as to kill much more than 50% of the cells. The acceptable lowest cell survival rate is around 45% for inclusion of the concentration levels for statistical analysis. Additional chambers of cells are included solely for obtaining the survival information for each concentration under each of the three testing conditions.

Statistical Analyses

The statistical analysis is conducted for each of the three test conditions separately. The compound is considered to have produced an effect if there is a statistically significant increase in the incidence of micronucleated cells in any of the three test conditions. Each binucleated cell examined is either a micronucleated cell with a fixed probability, p , or it is not, and the cells are independent from each other. The number of micronucleated cells, X , among a fixed number of cells, n , follows a binomial distribution as

$$X \sim B(n, p)$$

Therefore, for the i th concentration, $i = 1, 2, \dots, k$, the number of micronuclei, X_i , out of 2,000 binucleated cells is distributed as

$$X_i \sim B(n_i, p_i), \quad \text{for } i = 1, 2, \dots, k$$

where $n_i = 2,000$, and p_i being a fixed and unknown probability.

The evaluation of the compound effect on increases in the number of micronuclei out of 2,000 binucleated cells can be formulated as follows:

$$H_0 : p_1 = p_2 = \dots = p_k$$

vs.

$$H_a : p_1 \leq p_2 \leq \dots \leq p_k \text{ with at least one inequality.}$$

A linear contrast L_k in the proportions of a control, p_1 , and all concentration levels, $p_2, p_3, \dots, p_k$, can be specified to test the above hypotheses.^[12] Under the null hypothesis of no compound effect, the contrast should be 0, while under the alternative hypothesis of an increasing trend, the contrast should be positive. For example, for $k = 9$, the linear contrast, L_9 , is

$$L_9 = -4p_1 - 3p_2 - 2p_3 - 1p_4 + 0p_5 + 1p_6 + 2p_7 + 3p_8 + 4p_9$$

This test procedure can be carried out using PROC GENMOD in SAS.^[13] The binomial proportions are expressed by counts and total counts in a generalized linear model with a logit link function. The logit function is a one-to-one function that maps a proportion, p , from (0,1) to $(-\infty, \infty)$,

$$\text{logit}(p) = \log\left(\frac{p}{1-p}\right)$$

The concentration levels are included as a class variable in the model to reflect the log-scaled concentration levels. The fitted model is a saturated one because the number of parameters is the same as the number of observed proportions. The contrasts for increasing trends are defined by replacing the proportions in the above with their corresponding logits. These two formulations are equivalent because of the one-to-one correspondence between the proportion and the logit of the proportion. Contrasts for linear trends are evaluated by the likelihood ratio chi-square test. The resulting p values from the CONTRAST statements in PROC GENMOD are for two-sided tests. To determine the sign of the “slope” of the overall linear trend across all doses, one can obtain the estimate of the trend using the ESTIMATE statement. If the estimate of the trend is positive, then the one-sided p value is half of the p value reported from the CONTRAST statement. If the estimate of the trend is negative, then the one-sided p value is 1 minus half of the p value reported from the CONTRAST statement.

An alternate approach to testing for increasing trends in the proportions is to perform pairwise comparisons to the control. This approach is for testing any increase in the proportion at any concentration level compared to the control,

$$H_0 : p_1 = p_i, \quad i = 2, 3, \dots, k$$

vs.

$$H_a : p_1 < p_i \text{ for at least one } i = 2, 3, \dots, k$$

This pairwise comparison approach can be carried out using the GENMOD procedure as described for the trend test by modifying the contrasts to reflect the difference between the proportions from the i th concentration and the control

$$L_i = -1p_1 + 1p_i, \quad i = 2, 3, \dots, k$$

Similar to the trend test, the resulting p values from the CONTRAST statements in PROC GENMOD are for

two-sided tests. If the proportion of the i th concentration is greater than the proportion of the control, then the one-sided p value is half of the p value reported from the CONTRAST statement. Otherwise, the one-sided p value is 1 minus half of the p value reported from the CONTRAST statement.

For the pairwise comparison test, the type I error rate is inflated if no multiplicity adjustment is made. An adjustment by the Bonferroni approach^[14] can be carried out using PROC MULTTEST in SAS.^[15] The individual p values are multiplied by the number of the comparisons performed on the data. If the product is greater than 1, then the adjusted p value is defined to be 1. Therefore, a significant effect is declared for a compound only if the smallest unadjusted p value is below the predetermined type I error rate divided by the number of the comparisons made. In both the trend test and the pairwise comparison test, a one-sided test with a type I error rate of 0.05 is typically used.

Results—an Example

The results of an IVM test on hydrogen peroxide with cytochalasin B for the three test conditions are presented in Table 1. The numbers of micronucleated cells along with the p values from the trend tests as well as the unadjusted p values from the pairwise comparison tests are reported in Table 1. As six pairs of proportions are compared under the first two test conditions, each unadjusted p value was compared against 0.0083 as one-sixth of the familywise type I error rate of 0.05. The numbers of micronucleated cells are plotted against the ordinal concentration levels in Figs. 1–3.

For the 4- and 24-hour tests without metabolic activation, the concentration levels were from 0 up to 5 $\mu\text{g/mL}$, while the levels were up to 320 $\mu\text{g/mL}$ for the test with metabolic activation. This difference was driven by the criterion of having a survival rate of about 50% in the highest concentration to ensure a valid test design. In other words, to ensure that the cells were exposed to reasonably high concentrations of the chemical. For both the trend test and the pairwise comparison test, a highly significant effect was detected for either a 4- or 24-hour exposure to 5 $\mu\text{g/mL}$ of hydrogen peroxide without metabolic activation. However, no statistical significance was detected under the test condition of a 4-hour exposure with metabolic activation.

CONCLUSION

For validation purposes, 16 chemicals were evaluated by Garriott et al.^[4] using the two statistical approaches for assessing increases in the number of micronucleated cells. These 16 chemicals included non-genotoxins and direct- and indirect-acting genotoxins with various mechanisms

Table 1 Summary of *p* Values from Statistical Analyses on the Numbers of Micronucleated Cells in 2,000 Binucleated Cells Tested in Hydrogen Peroxide with Cytochalasin B

NT: Not tested.

For the 4- and 24-hour tests without metabolic activation, the concentration levels were from 0 up to 5 µg/mL while for the 4-hour test with metabolic activation, the concentration levels were 0 and 0.16 up to 320 µg/mL.

^aStatistically significant increasing trend detected at the 0.05 level (*p* value ≤ 0.05).

^bStatistically significant increases detected at the 0.05 level (unadjusted *p* value ≤ 0.0083 = 0.05/6).

**Fig. 1** Number of micronuclei out of 2,000 binucleated cells after a 4-hour exposure to hydrogen peroxide without metabolic activation and in the presence of cytochalasin B**Fig. 2** Number of micronuclei out of 2,000 binucleated cells after a 24-hour exposure to hydrogen peroxide without metabolic activation and in the presence of cytochalasin B

of action and different levels of genotoxic potency. There was total agreement between the two statistical tests in declaring statistical significance of the chemicals for all three metabolic activation conditions in the presence of cytochalasin B. In general, for chemicals that cause chromosomal damage and interact with the mitotic spindle apparatus, the number of micronuclei usually increases as the concentration increases. Otherwise, the number of

micronuclei fluctuates around the control range and exhibits no positive trend. As the trend test is more powerful in detecting increasing trends than the pairwise comparison test, it is the natural choice for analysis of data from the IVM test for routine screening of chemicals. However, one can also consider using the trend test as the primary test for detecting monotonically increasing trends while keeping the pairwise comparison test as a backup test for

Fig. 3 Number of micronuclei out of 2,000 binucleated cells after a 4-hour exposure to hydrogen peroxide with metabolic activation and in the presence of cytochalasin B

cases when the trend is not significant but there appear to be significant increases at lower concentrations.

Although concurrent controls are always included in the IVM test and also in the evaluation of the effect of the chemical, variation from test to test can be assessed from historical control counts. It will be beneficial for data checking and interpretation of the test results if reference ranges for the control counts are established.

Other statistical analyses for evaluating an increasing trend in the binomial proportions include the Cochran-Armitage trend test^[16,17] and logistic regression modeling with the actual or log concentration levels as a regressor. The trend test carried out as described in this article is reasonably straightforward and resulted in consistent conclusions on most of the chemicals. On occasions when the trend test may appear to be either too sensitive or too insensitive, historical data should be referenced to help interpret the observed results.

Abstract

This entry outlines the limitation of average bioequivalence for the assessment of drug interchangeability, reviews the decision rules, and statistical methods for evaluation of individual bioequivalence, and provides a comprehensive review of FDA guidelines.

INTRODUCTION

The current concept for the assessment of bioequivalence (BE) is based on the *Fundamental Bioequivalence Assumption* that when two formulations of the same drug product or two drug products (e.g., a brand name drug and its generic copy) are equivalent in the rate and the extent of drug absorption, it is assumed that they will reach the same therapeutic effect or that they are therapeutically equivalent.^[1] Pharmacokinetic (PK) responses, such as area under the plasma or blood concentration–time curve (AUC) and maximum concentration ($C_{\max}$), are usually considered to assess the rate and the extent of drug absorption. The U.S. Food and Drug Administration (FDA) requires that evidence of BE in average bioavailabilities in terms of some primary PK responses such as AUC and $C_{\max}$ between the two formulations of the same drug product or the two drug products be provided.^[2,3] This type of BE is referred to as *average bioequivalence* (ABE).

In the medical community, as more generic drug products become available in the marketplace, it is of great concern whether a number of generic drug products of the same brand name drug can be used safely and interchangeably. Basically, drug interchangeability can be classified as drug prescribability or drug switchability. Drug prescribability is defined as the physician's choice for prescribing an appropriate drug product for the physician's patients between a brand name drug product and a number of generic drug products of the brand name drug product that have been shown to be bioequivalent to the brand name drug product. The underlying assumption of drug prescribability is that the brand name drug product and its generic copies can be used interchangeably in terms of efficacy and safety of the drug product. However, ABE does not take into account the equivalence in variability of bioavailability. A relatively large intra-subject variability

of a test drug product (e.g., a generic drug product) compared to that of the reference drug product (e.g., its brand name drug product) may present a safety concern. To overcome this disadvantage, in addition to providing evidence of ABE, it is recommended that BE in variability of bioavailabilities between drug products be established. This type of BE is called *population bioequivalence* (PBE). In practice, although PBE is often considered for the assessment of drug prescribability, it does not fully address drug switchability because of the possible existence of subject-by-formulation interaction.

Drug switchability is related to the switch from a drug product (e.g., a brand name drug product) to an alternative drug product (e.g., a generic copy of the brand name drug product) within the same subject, whose concentration of the drug product has been titrated to a steady, efficacious, and safe level. As a result, drug switchability is considered more critical than drug prescribability in the study of drug interchangeability for patients who have been on medication for a while. To ensure drug switchability, it is recommended that BE be assessed within individual subjects. This type of BE is known as *individual bioequivalence* (IBE). In "Limitations of Average Bioequivalence," the limitation of ABE for the assessment of drug interchangeability is outlined. The concepts, decision rules, and statistical methods for evaluation of IBE (as described in the 2001 FDA guidance) are given in the section "Individual Bioequivalence." In "Review of the 2001 FDA Guidance," a comprehensive review of the FDA guidances will be provided. A brief summary is given in the "Conclusion."

LIMITATIONS OF AVERAGE BIOEQUIVALENCE

Under ABE, two formulations of the same drug or two drug products are claimed bioequivalent if the ratio of the

means of the primary PK responses between two formulations is within (80%, 125%), with a 90% assurance^[3] It follows that under an ABE criterion, a generic drug product can be used as a substitution for a brand name drug if it has been shown to be bioequivalent to the brand name drug based on average bioavailability. However, the FDA does not indicate that two generic drug products of the same brand name drug can be used interchangeably, even when they are shown to be, on average, bioequivalent to the same brand name drug. In addition, the FDA does not require that the evidence of ABE among generic copies of the same brand name drug be provided. As more generic drugs become available in the marketplace, it is very likely that a patient may switch from one generic drug to another. Therefore an interesting question to physicians and patients is whether the brand name drug and its generic copies can be used safely and interchangeably.

Chen^[4] pointed out that the ABE criterion for the assessment of BE has limitations for addressing drug interchangeability, especially for drug switchability. These limitations include: (i) ABE focuses only on the comparison of population average between the test product and the reference drug product; (ii) the distribution of the primary PK responses of interest is not taken into account, nor is the intrasubject variance of the drug product under study; and (iii) the ABE criterion ignores the subject-by-formulation interaction, which has an impact on drug switchability. As a result, Chen^[4] suggested that the ABE criterion be switched to the IBE approach to overcome these disadvantages.

Many practitioners, however, indicated that the impact of the foregoing limitation on safety might be negligible because little clinical evidence was observed in the past decade to demonstrate that the generic drugs approved based on the ABE criterion were unsafe. In addition, if the limitations of the ABE criterion do have an impact on safety, it is recommended that the decision rule (i.e., the one-fits-all BE limits) of ABE be modified before switching to a totally new, and yet much more complicated, approach of IBE. For example, if the safety of the drug product under study is a great concern, we may lower the upper BE limit from, say, 125–115%. Similarly, we may adjust the lower BE limit to ensure the efficacy. This flexibility not only reflects the nature of the drug product under the study, but also allows a more accurate and reliable assessment of BE between drug products. The adjustment of BE limits of ABE should be flexible according to drug classification, which may depend upon either (i) the intrasubject variability and the therapeutic window of the drug product, or (ii) the population difference ratio (PDR) and/or the individual difference ratio (IDR) as specified in the FDA guidance.^[5]

Chow and Liu^[6] proposed to perform a meta-analysis for an overview of ABE. The proposed meta-analysis provides an assessment of BE among generic copies of an innovative drug that can be used as a tool in monitoring the performance of the approved generic copies of the

innovative drug. In addition, it provides more accurate estimates of intersubject and intrasubject variability of the drug products.

INDIVIDUAL BIOEQUIVALENCE

Individual Bioequivalence Criterion

As indicated earlier, switchability evaluates drug interchangeability within the same patients through the concept of IBE. Individual bioequivalence is originally motivated by the so-called “75/75 rule,” which claims BE if at least 75% of individual subject ratios (i.e., relative individual bioavailability of the generic drug product to the innovative drug product) are within (75%, 125%) limits. Along with this line, Anderson and Hauck^[7] proposed the concept of testing individual equivalence ratio (TIER). The idea is to test IBE based on the dichotomization of continuous PK metrics by calculating the *P* value for at least the observed number of subjects who fall within the BE limit with the minimum proportion of the population in which two drug products must be equivalent in order to claim IBE.

It should be noted that no universal definition of IBE exists that is uniformly accepted by researchers from the regulatory agency, the academia, and the pharmaceutical industry. For example, IBE may be established based on the comparison between distributions within each subject, or it could be based on the distribution of the difference or ratio within each subject.^[8] In addition to average bioavailability, we may also consider the assessment for the variability of bioavailability and the variability due to subject-by-formulation interaction. This disaggregated approach to evaluation of IBE can be assessed by means of intersection–union test (IUT) principle.^[9] Under the disaggregated approach, IBE is concluded if and only if all of the three hypotheses are rejected at the α level of significance. Although the disaggregate approach is a level α test, it can be very conservative.

On the other hand, IBE can also be evaluated using the aggregated approaches that are derived from the distribution of either the difference or the ratio within each subject. Under the aggregated approach, the criteria for assessment of IBE can be classified as probability-based and moment-based criteria (e.g., Refs. [7,10–14]). To address drug switchability, the FDA stressed that the comparisons of interest should be expressed in terms of the ratio of the expected squared difference between the test (T) product and the reference (R) product (administered to the same subject) and the expected squared difference between two administrations of the reference product to the same subject. The square root of this ratio is called the IDR:

$$\begin{aligned} \text{IDR} &= [E(T - R)^2 / E(R - R)^2]^{1/2} \\ &= [(\mu_T - \mu_R)^2 + \sigma_D^2 + (\sigma_{WT}^2 + \sigma_{WR}^2) / 2\sigma_{WR}^2]^{1/2} \end{aligned}$$

where μ_T and μ_R are the averages of the test and reference drug products, respectively; σ_{WT}^2 and σ_{WR}^2 are the intra-subject variability of the test and reference drug products, respectively; and σ_D^2 is the variance as a result of the subject-by-formulation interaction.

Based on the IDR, the U.S. FDA proposed the following aggregated, mixed-scaled, moment-based, one-sided individual bioequivalence criterion (IBC):

$$IBC = \left[(\mu_T - \mu_R)^2 + \sigma_D^2 + 0 \sigma_{WT}^2 + \sigma_{WR}^2 / \max(\sigma_{WR}^2, \sigma_{WO}^2) \right]$$

where σ_{WO}^2 is a constant that can be adjusted to control the probability of passing IBE.

It follows that the hypothesis for the evaluation of IBE can be formulated as:

$$H_0 : IBC \geq \theta_1 \text{ vs. } H_a : IBC < \theta_1$$

where θ_1 is the IBE limit.

When $\sigma_{WR}^2 > \sigma_{WO}^2$, the IBC used is scaled to the variability of the reference formulation and is referred to as the reference-scaled IBC. On the other hand, when $\sigma_{WR}^2 \leq \sigma_{WO}^2$, it is called the constant-scaled IBC. The reasons for the mixed-scaled IBC recommended in the 2001 FDA guidance are twofold. First, in general, the reference-scaled IBC effectively widens the BE limits for more variable reference products. Secondly, for drug products with low variability but a wide therapeutic range, the reference-scaled IBC can unnecessarily narrow the BE limit. In this case, the constant-scaled IBC is used.

When the reference-scaled IBC is used, the relationship between IDR and IBC can be described by the following equation:

$$IDR = (IBC/2 + 1)^{1/2}$$

As a result, assuming that the maximum allowable IDR is 1.25, the 2001 FDA guidance recommends that $\sigma_{WO} = 0.2$. On the other hand, the determination of θ_1 should be based on the consideration of both ABE criterion and variance terms in the IBE criterion as formulated as follows:

$$\theta_1 = \left[(\ln 1.25)^2 + \varepsilon_1 \right] / \sigma_{WR}^2$$

where ε_1 is the variance allowance factor. The U.S. guidance suggests that the allowance for the variance terms $\sigma_{WT}^2 - \sigma_{WR}^2$ and σ_D^2 be 0.02 and 0.03, respectively. The choice of σ_D^2 being 0.03 implies that when $\mu_T - \mu_R = 0$, the probability that individuals would have their average ratio outside ABE limits (0.8, 1.25) is around 80%. Consequently, the 2001 FDA guidance recommends that $\sigma_{WR} = 0.2$ and:

$$\begin{aligned} \theta_1 &= \left[(\ln 1.25)^2 + \varepsilon_1 \right] / \sigma_{WR}^2 \\ &= [0.0498 + 0.05] / 0.04 \\ &= 2.495 \\ &\approx 2.5 \end{aligned}$$

The decision rule recommended by the 2001 FDA guidance is to conclude IBE if and only if the 95% upper confidence bound for IBC is less than 2.5 and the point estimate of the geometric mean ratio of the test drug product to the reference drug product falls within 80–125%.

The 2001 FDA guidance recommends a statistical method proposed by Hylop et al.^[15] for the construction of the 95% confidence bound for the linearized IBC, which is given as:

$$LIBC = (\mu_T - \mu_R)^2 + \sigma_D^2 + (\sigma_{WT}^2 + \sigma_{WR}^2) - 2.5 \times \max(\sigma_{WR}^2, 0.04)$$

and the corresponding hypothesis is reformulated as:

$$H_0 : LIBC \geq 0 \text{ vs. } H_a : LIBC < 0$$

It follows that IBE is concluded if and only if the 95% upper confidence bound for LIBC is less than 0 and the point estimate of the geometric mean ratio of the test drug product to the reference drug product falls within 80–125%.

Statistical Method

The 2001 FDA guidance provides a detailed description of the statistical steps for the construction of 95% confidence bound for LIBC under the two-sequence and four-period (2×4) replicated crossover design (TRTR, RTRT).^[15] It is suggested that the methods of moments and the restricted maximum likelihood method for the estimation of the mean and variance parameters in IBE approach be used. The recommended statistical procedure for the 2×4 replicated crossover design is outlined below (see also Ref. [16]).

Consider the following statistical model that assumes a four-period design with an equal replication of T and R in each of s sequences with an assumption of no or equal carryover effects:

$$Y_{ijkl} = \mu_k + \gamma_{ikl} + \delta_{ijk} + \varepsilon_{ijkl}$$

where $i = 1, \dots, s$ indicates sequence; $j = 1, \dots, n_i$ indicates subject within sequence i ; $k = R, T$ indicates treatment; $l = 1, 2$ indicates replicates on treatment k for subjects within sequence i . Y_{ijkl} is the response of replicate l on treatment k for subject j in sequence i ; γ_{ikl} represents the fixed effect of replicate l on treatment k in sequence i ; δ_{ijk} is the random subject effect for subject j in sequence i on treatment k ; and ε_{ijkl} is the random error for subject j within sequence i on replicate l of treatment k . The ε_{ijkl} s are assumed to be mutually independent and identically distributed as:

$$\varepsilon_{ijkl} \sim N(0, \sigma_{WK}^2)$$

for $i = 1, \dots, s$; $j = 1, \dots, n_i$; $k = R, T$; and $l = 1, 2$. Also, the random subject effects $\delta_{ij} = (\mu_R + \delta_{ijR}, \mu_T + \delta_{ijT})'$ are assumed to be mutually independent and distributed as:

$$\delta_{ij} \sim N_2 \left[\begin{pmatrix} \mu_R \\ \mu_T \end{pmatrix}, \begin{pmatrix} \sigma_{BR}^2 & \rho\sigma_{BT}\sigma_{BR} \\ \rho\sigma_{BT}\sigma_{BR} & \sigma_{BT}^2 \end{pmatrix} \right]$$

The following constraint is applied to the nuisance parameters to avoid an overparameterization of the model for $k = R, T$:

$$\sum_{i=1}^s \sum_{l=1}^2 \gamma_{ikl} = 0$$

In order to estimate the linearized criteria, define:

$$\begin{aligned} I_{ij} &= Y_{ijT} - Y_{ijR} \\ T_{ij} &= Y_{ijT1} - Y_{ijT2} \\ R_{ij} &= Y_{ijR1} - Y_{ijR2} \end{aligned}$$

for $i = 1, \dots, s$ and $j = 1, \dots, n_p$ where:

$$Y_{ijT} = \frac{1}{2}(Y_{ijT1} + Y_{ijT2}) \text{ and } Y_{ijR} = \frac{1}{2}(Y_{ijR1} + Y_{ijR2})$$

Compute the formulation means and the variances of I_{ij} , T_{ij} , and R_{ij} , pooling across sequences, and denote these variance estimates by M_1 , M_T , and M_R , respectively, where:

$$\begin{aligned} \hat{\mu}_k &= 1/s \sum_{l=1}^s \bar{Y}_{ik} \quad (k = R, T) \text{ and } \hat{\Delta} = \hat{\mu}_T - \hat{\mu}_R \\ \bar{Y}_{ik} &= \frac{1}{n} \sum_{j=1}^{n_j} \frac{1}{2} \sum_{l=1}^2 Y_{ijkl} \\ M_1 &= \hat{\sigma}_1^2 = \frac{1}{n_I} \sum_{i=1}^s \sum_{j=1}^{n_j} (I_{ij} - \bar{I}_i)^2 \\ n_1 &= n_T = n_R = \left(\sum_{i=1}^s n_i \right) - s \\ M_T &= \hat{\sigma}_{WT}^2 = \frac{1}{2n_T} \sum_{i=1}^s \sum_{j=1}^{n_j} (T_{ij} - \bar{T}_i)^2 \\ M_R &= \hat{\sigma}_{WR}^2 = \frac{1}{2n_R} \sum_{i=1}^s \sum_{j=1}^{n_j} (R_{ij} - \bar{R}_i)^2 \end{aligned}$$

Then, the linearized criteria can be estimated by:

a. Reference scale:

$$\hat{n}_1 = \hat{\Delta}^2 + M_1 + 0.5M_T - (1.5 + \theta_1)M_R$$

b. Constant scale:

$$\hat{n}_2 = \hat{\Delta}^2 + M_1 + 0.5M_T - 1.5M_R - \theta_1\sigma_{W0}^2$$

and the subject-by-formulation interaction variance component can be estimated by:

$$\hat{\sigma}_D^2 = \hat{\sigma}_1^2 - \frac{1}{2}(\hat{\sigma}_{WT}^2 + \hat{\sigma}_{WR}^2)$$

As a result, a 95% upper confidence bound for the reference-scaled criterion can be obtained as:

$$Hn_1 = \sum E_q + \left(\sum U_q \right)^{1/2}$$

where E_q and U_q are defined and given in the following table:

$H_q = \text{confidence bound}$	$E_q = \text{point estimate}$	$U_q = (H_q - E_q)^2$
$H_D = \left(\left \bar{\Delta} \right + t_{1-\alpha, n-s} \times \left(\frac{1}{S^2} \sum_{j=1}^s n_j^2 M_1 \right)^{1/2} \right)^2$	$E_D = \hat{\Delta}^2$	U_D
$H_1 = \frac{(n-s)M_1}{\chi_{\alpha, n-s}^2}$	$E_1 = M_1$	U_1
$H_T = \frac{0.5(n-s)M_T}{\chi_{\alpha, n-s}^2}$	$E_T = 0.5M_T$	U_T
$H_R = \frac{-(1.5 + \theta_1)(n-s)M_R}{\chi_{1-\alpha, n-s}^2}$	$E_R = -(1.5 + \theta_1)M_R$	U_R
$H_{n1} = \sum E_q + \left(\sum U_q \right)^{1/2}$		

Similarly, a 95% upper confidence bound for the constant scale is given by:

$$H_{n2} = \sum E_q - \theta_1\sigma_{W0}^2 + \left(\sum U_q \right)^{1/2}$$

where E_q and U_q are specified in the following table:

$H_q = \text{confidence bound}$	$E_q = \text{point estimate}$	$U_q = (H_q - E_q)^2$
$H_D = \left(\left \bar{\Delta} \right + t_{1-\alpha, n-s} \times \left(\frac{1}{S^2} \sum_{j=1}^s n_j^2 M_1 \right)^{1/2} \right)^2$	$E_D = \hat{\Delta}^2$	U_D
$H_1 = \frac{(n-s)M_1}{\chi_{\alpha, n-s}^2}$	$E_1 = M_1$	U_1
$H_T = \frac{0.5(n-s)M_T}{\chi_{\alpha, n-s}^2}$	$E_T = 0.5M_T$	U_T
$H_R = \frac{-(1.5)(n-s)M_R}{\chi_{1-\alpha, n-s}^2}$	$E_R = -(1.5)M_R$	U_R
$H_{n2} = \sum E_q - \theta_1\sigma_{W0}^2 + \left(\sum U_q \right)^{1/2}$		

REVIEW OF THE 2001 FDA GUIDANCE

In October 2002, the U.S. FDA issued a draft guidance on *Bioavailability and Bioequivalence Studies for Orally Administered Drug Products—General Considerations*.^[3] This guidance presents a unified approach to meet the requirements set forth in 21 CFR Part 30 as applied to dosage forms intended for oral administration. As a result, this guidance is to replace a number of previously issued FDA drug-specific BE guidances, including the guidance on statistical approaches issued in July 1992.^[2] In addition, in January 2001, the U.S. FDA issued a guidance on *Statistical Approaches to Establishing Bioequivalence*.^[5] This guidance provides the BE criteria and their corresponding statistical procedures for ABE, PBE, and IBE as present in the guidance for general considerations. In what follows, we provide a comprehensive review of the FDA guidance on *Statistical Approach to Assessing Bioequivalence* from both scientific/statistical and practical points of view (see also Ref. [17]).

Aggregated Criteria Vs. Disaggregated Criteria

The 2001 FDA guidance recommends aggregated criteria as described earlier for the assessment of IBE. In addition to the average of bioavailability, the IBE criterion takes into account the variability of bioavailability, as well as the variability because of the subject-by-formulation interaction. Although the FDA requires that the point estimate of the geometric mean ratio between test product and reference product be within 80–125% when using the IBE approach under the proposed aggregated criteria, it is not clear whether the IBE criterion is superior to the ABE criterion in the assessment of drug exchangeability. In other words, it is not known whether or not IBE implies ABE under aggregated criteria. Hence, the question of particular interest to pharmaceutical scientists is whether the proposed IBE criterion can really address the drug-to-drug interchangeability (i.e., drug switchability).

Liu and Chow^[8] suggested that disaggregated criteria be implemented for the assessment of drug interchangeability. In addition to ABE, the disaggregated criteria may consider the following hypothesis testing for assessing BE in the variability of bioavailability and variability due to the subject-by-formulation interaction:

$$H_0 : \sigma_{WT}^2 / \sigma_{WR}^2 \geq \Delta_v \text{ vs. } H_0 : \sigma_{WT}^2 / \sigma_{WR}^2 < \Delta_v$$

and

$$H_0 : \sigma_D^2 \geq \Delta_s \text{ vs. } H_a : \sigma_D^2 < \Delta_s$$

where Δ_v is the BE limit for the ratio of intrasubject variability and Δ_s is an acceptable limit for variability due to subject-by-formulation interaction. We conclude IBE if and only if the 90% confidence interval for μ_T/μ_R is within

(80%, 125%), and both the 95% upper confidence limit for $\sigma_{WT}^2/\sigma_{WR}^2$ is less than Δ_v and the 95% upper confidence limit for σ_D^2 is less than Δ_s . Under the disaggregated criteria, it is clear that IBE implies ABE.

In practice, it is then of interest to examine the relative merits and disadvantages of the FDA-proposed aggregated criteria and disaggregated criteria described early for the assessment of drug interchangeability. In addition, it is also of interest to compare the aggregated and disaggregated criteria of PBE and IBE with the conventional ABE criterion in terms of the consistencies and inconsistencies in concluding BE for regulatory approval.

Interpretation of the Criteria

The guidance suggests that a logarithmic transformation be performed for all BE measures (e.g., AUC and C_{max}). For ABE, the interpretation on both the original and the log scale is straightforward and easily understood, because the difference in arithmetic means on the log scale is the ratio of geometric means on the original scale. For log transformation, two drug products are concluded ABE if the ratio of the average bioavailabilities on the original scale is between 80% and 125%. This statement is the same as saying that the two drug products are concluded ABE if the difference between the arithmetic means on the log scale is between $-0.2231 (= \ln(0.8))$ and $0.2231 (= \ln(1.25))$. On the other hand, the interpretation of the aggregate criteria for IBE is not straightforward and clear on both scales. For example, the exponentials of the subject-by-formulation interaction and intrasubject variability on the log scale do not correspond to the subject-by-formulation interaction and intrasubject variability on the original scale. In addition, more detailed explanations and sufficient reasons should be given as to why $\sigma_{WT}^2 - \sigma_{WR}^2 = 0.02$ and $\sigma_D^2 = 0.03$ are chosen for θ_1 and their interpretation on the original scale.

Masking Effect

The goal for evaluating BE is to assess the similarity of the distributions of the PK measures obtained either from the population or from individuals in the population. However, under aggregate criteria, different combinations of values for the components of the aggregate criterion can yield the same value. In other words, BE can be reached by two totally different distributions of PK measures. At the 1996 Advisory Committee meeting, it was reported that the data sets from the FDA's files show that a 14% increase in average (ABE allows only 80–125%) is offset by a 48% reduction in the variability, and the test passes IBE but fails ABE. The current requirement of the 2001 FDA guidance on IBE cannot alleviate the above situation because it only requires that the point estimates of the geometric test/reference mean be within 80–125% in addition to meeting the 95% confidence bound for IBE being less than 2.5.

Power and Sample Size Determination

For the proposed aggregated criterion, it is desirable to have sufficient statistical power to declare IBE if the value of the aggregated criterion is small. On the other hand, we would not want to declare IBE if the value is large. In other words, a desirable property for the assessment of BE is that the power function of the statistical procedure is monotone decreasing function. However, because different combinations of values of the components in the aggregated criteria may reach the same value, the power function for any statistical procedures based on the aggregated criteria is not a monotone decreasing function. Another major concern is how the aggregated IBC will affect the sample size determination based on the power analysis. Unlike ABE, the relationship between the power and the parameters are complicated and there exists no closed form for the power function of the statistical procedure proposed by Hylop et al.^[15] for IBE. As a result, the 2001 FDA guidance states that the sample size for individual BE should be based on simulated data.

Chow et al.^[16] indicated that for a given set of parameter $(\Delta, \rho, \sigma_{BT}, \sigma_{BR}, \sigma_{WT}, \sigma_{WR})$, under the assumption that:

$$\eta = \Delta^2 + \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho\sigma_{BT}\sigma_{BR} + \sigma_{WT}^2 - \sigma_{WR}^2 - \theta_{IBE} \max\{\sigma_0^2, \sigma_{WR}^2\} < 0$$

The n (the sample size per sequence) needed to achieve a given power p can be estimated by the first integer (n) satisfying the following inequality:

$$\eta + \sqrt{U_p} + \sqrt{U_{0.95}} < 0$$

where $U_p = U_D + U_1 + U_T + U_R$. More details regarding sample size calculation for IBE can be found in Chow and Shao^[18] and Chow et al.^[16]

Note that different combinations of $\mu_T - \mu_R$, σ_D , σ_{WT} , and σ_{WR} could lead to the same value of LIBC and yet the sample size required for achieving the desired power may be different. For example, combinations of $\mu_T - \mu_R$, σ_D , σ_{WT} and $\sigma_{WR} = (0.2, 0, 0.2, 0.2)$, $(0, 0.2, 0.15, 0.15)$, and $(0, 0.2, 0.2, 0.2)$ will give the same value of LIBC (i.e., -0.0598) but different sample sizes per sequence 52, 20, and 59, respectively, are required.^[16]

Two-Stage Test Procedure

To apply the IBC for the assessment of IBE, the 2001 FDA guidance suggests that the constant scale be used if the observed estimator of σ_{WR} is smaller than 0.2. However, statistically, the observed estimator of σ_{WR} being smaller than 0.2 does not mean that σ_{WR} is smaller than 0.2. A test on the null hypothesis that σ_{WR} is smaller than 0.2 should be performed. As a result, the proposed statistical procedure for the assessment of IBE becomes a two-stage test

procedure. It is then recommended that the overall type I error rate and calculation of power be adjusted accordingly.

Study Design

The 2001 FDA guidance recommends that two replicated designs, i.e., (ITRTR, RTRT) and (TRT, RTR), be used for the assessment of IBE. It is not clear whether the two replicated crossover designs are the optimal design in terms of power or variance in 2×4 and 2×3 replicated crossover designs with respect to the aggregated criteria. In addition, the 2001 FDA guidance indicates that the 2×4 (TRTR, RTRT) design be recommended, while the 2×3 (TRT, RTR) design is preferred as an alternative. Several questions are raised. First, it is not clear what the relative efficiency of the two designs is if the total number of observation is to be fixed? Secondly, it is not clear how these two designs compare to other 2×4 and 2×3 replicated designs such as (TRRT, RTRT) and (TTRR, RRTT) designs, and (TRR, RRT) and (TTR, RRT) designs. Finally, it may be of interest to study the relative merits and disadvantages of these two designs as compared to other designs, such as Latin square designs and four-sequence and four period designs.

Other issues regarding the proposed replicated designs include the following: (i) it will take a longer time to complete; (ii) the subject's compliance may be a concern; (iii) it is likely to have a higher dropout rate and missing values, especially in 2×4 designs; and (iv) there is little in the literature on statistical methods that deals with dropouts and missing values in a replicated crossover design setting.

Outlier Detection

No formal statistical procedure for the detection of outliers for the standard 2×2 crossover designs or for the 2×3 and 2×4 replicated crossover design has been suggested in the 2001 FDA guidance. For a valid statistical assessment, the procedures proposed by Chow and Tse^[19] and Liu and Weng^[20] should be used. These proposed statistical procedures for outlier detection in BE studies were derived under crossover designs that incorporate the correlations with the same subject. The guidance provides little or no discussion regarding the treatment of identified outliers.

CONCLUSION

The rationale for switching from ABE to IBE lacks (i) convincing clinical evidence regarding the limitations of ABE for addressing drug interchangeability, and (ii) a valid scientific/statistical justification for IBE. It is then recommended that clinical evidence for the limitations of ABE and scientific/statistical justification of IBE be carefully evaluated before the IBE criteria and corresponding statistical procedure be implemented for the replacement of ABE as the standard requirement for the assessment of BE.

To provide convincing clinical evidence regarding the limitations of ABE for addressing drug interchangeability, it would be helpful to study the incidence rates concerning the failure or critical safety issue of approved generic drug products in the past decade. A high incidence rate may indicate that there is a deficiency in the current regulation of ABE. If the incidence is relatively low and is considered clinically acceptable, then there is no need to switch from ABE to IBE, especially when clinical performance is unknown. On the other hand, to provide scientific/statistical justification for the use of IBE, it is suggested that the probabilities of consistencies and inconsistencies for BE assessment of ABE and IBE be evaluated.^[8] If the probability of consistency between ABE and IBE is high and the probability of inconsistency is low, then there is no need to switch from ABE to IBE because ABE and IBE will basically reach the same conclusion regarding BE. If there is a relatively high probability of inconsistency between ABE and IBE with a relatively low probability of consistency between ABE and IBE, then the impact on clinical performance for the switch from ABE to IBE is necessarily provided. In this case, instead of switching from ABE to IBE, we might tighten the BE limits for ABE to achieve the same result as IBE.

In addition to efficacy and safety, the identity, strength, purity, and stability of approved generic drug products are important drug characteristics that have an impact on average bioavailability, variability of bioavailability, and variability due to subject-by-formulation interaction and consequently drug interchangeability. As a result, it is suggested that the regulatory requirements for post-approval equivalence in the laboratory development and the manufacturing process be established regardless of the switch from ABE to IBE.

More information regarding the relative merits and disadvantages of ABE and IBE can be found in a special issue of *Clinical Pharmacology Therapy and Toxicology on Bioequivalence Assessment: Methods and Applications*,^[21] a special issue of *Drug Information Journal on Bioavailability and Bioequivalence*,^[22] the proceedings of FIP Bio-International '96 Bioavailability, Bioequivalence and Pharmacokinetics, a special issue of *Journal of Bio-pharmaceutical Statistics*,^[23] a special issue of *Statistics in Medicine in individual Bioequivalence*,^[14] and a reference book on statistical design and analyses for the evaluation of BE.^[1]

Abstract

This entry provides an overview of both qualitative and quantitative approaches to the development and validation of psychometric instruments.

Keywords: Development; Psychometric instrument; Validation.

INTRODUCTION

A psychometric instrument can provide a standardized and objective means of collecting data on subjective states or events. Literally thousands of such instruments exist, ranging from ad hoc instruments composed by investigators for one time use up to rigorously developed and validated instruments used over decades for research and evaluation.^[1–5] Despite the large number, variety, and widespread availability of these instruments, investigators frequently face the need to develop new ones. This need arises because a proper development and validation of the existing instruments was achieved for a specific purpose and relative to a defined population. While the existing pool of instruments will often contain one that has been developed in the population of interest for the purpose desired, new research questions will just as often require new instruments for measurement. Development for a defined purpose and in a defined population is the only way to ensure a proper sampling and a valid measurement of the content of the subjective state, behavior, or disease to be measured.

OVERVIEW

This article provides an overview of both qualitative and quantitative approaches to the development and validation of psychometric instruments.

The approach to inventory development discussed in the first edition of this article had three major steps. The first step was the patient generation of items or questions for the inventory and their arrangement into groups of apparently related items, called domains, for potential inclusion in the final inventory. The second step was the qualitative content validation of the items and domains. The third step was the quantitative psychometric item analysis, which was used to select an optimum subset

of items and to determine domain structure. Methods to assess the developed instrument's reliability and validity were additionally discussed.

Two major additions have been made. The first is the use of Confirmatory Factor Analysis (CFA) to assess how well a hypothesized factor structure fits a new set of data. This new set of data may be a new sample from the same population, in order to confirm the identified factor structure during the exploratory phase, or may represent a different population in order to assess whether the factor structure fits this new population.

Additionally, a major advance in the area of measurement development that will also be discussed in this update is Item Response Theory (IRT). The first edition to this article was restricted to classical test theory methods while this updated version will expand into IRT methods.

Where appropriate, examples will be provided from the development of the Profile of Female Sexual Function© (PFSF), a multinational, patient-generated inventory for the measurement of hypoactive sexual desire (hypoactive sexual desire disorder, HSDD; see DSM-IV, Ref. [6]), or low desire, in menopausal women. This instrument was developed and validated among menopausal women having HSDD for the purpose of measuring the response to therapy in clinical trials of novel therapeutic agents. Although a large number of sexual function measurement tools exist,^[2] before the present work was done, no properly developed instrument for HSDD was in existence. Since the first edition, articles detailing the development and validation of the PFSF have been published.^[7,8]

The discussion on instrument development in this article focuses on the qualitative and quantitative aspects of questionnaire development, validation and refinement. Discussions of other important topics in instrument development, such as scale selection, recall period, response set, sampling, and related issues, can be found in many of the references cited here.

ITEM GENERATION

The objective of item generation is to establish a preliminary inventory that has face and content validity. This process must ensure the proper identification of the characteristics of the disease to be measured and an adequate sampling of their content to allow a valid measurement.

Face validity is that characteristic of an item which, “on the face of it,” appears to be relevant to the outcome it intends to capture. For example, if sexual desire is being measured, then items should look like they are addressing the characteristics of sexual desire and not some other concept, such as marital happiness. In most cases, this is a necessary characteristic for a valid instrument. However, there are instances where this characteristic may not be desired or needed. For example, instruments ascertaining a sensitive subject (e.g., substance abuse) may try to elicit responses in a more indirect manner if it is felt that a subject will not answer direct questions truthfully.^[9]

Content validity refers to the instrument property of a proper sampling of items, presentation, and the measurement of all aspects of the disease or other states relevant to the patient. Items should reflect the medical diagnosis of the disease as well as patients’ thoughts, feelings, and emotions as affected by the disease. This is generally a qualitative process that speaks to the sampling and the presentation of the items in an inventory.^[1,9] A detailed discussion of item generation and domain identification can be found in Nunnally and Bernstein,^[9] Juniper et al.,^[10] and McHorney,^[11] among others. Although this is generally addressed qualitatively, a quantitative method referenced in Streiner and Norman 4th edition^[12] is the content validity index (CVI). Here a group of experts rate the relevance of an item to a domain on a scale of 1, totally irrelevant, to 4, extremely relevant. CVI is the proportion of experts who rate the item a 3 or 4. Guidelines for acceptance of an item are given in Lynn.^[13] See Haynes et al.^[14] for a comprehensive guide for determining content validity.

There are numerous methods for item development. Two publicly available item pools are the International Personality Item Pool (IPIP) (<http://ipip.ori.org>) and PROMIS (Patient-Reported Outcomes Measurement Information System). [15–17] IPIP provides both items and scales measuring personality traits such as assertiveness, anger, and compassion. PROMIS is an initiative of the NIH to develop item banks to measure patient reported outcomes in pain, fatigue, emotional distress, physical functioning, social role participation, and general health perception.

Other methods of item generation include the development based on literature review and an understanding of the disease, the discussions among experts or a direct development of items by experts, the factor analytic methods applied to data from previously existing instruments, and the direct development by patients. The patient identification of domains and the generation of inventory items have numerous advantages.^[11,18] Patient-generated

items are: (i) directly reflective of patients’ experiences and perspectives and therefore have a high degree of face validity; (ii) more likely to be acceptable to patients in terms of their content and reading level; and (iii) more likely to ensure that investigators and patients have a single and common understanding of the item and domain meanings.

The use of literature and professional input alone is often not sufficient and may suffer from the phenomenon exemplified by the game of “telephone” in which the meaning of a message changes as it is passed along from person to person. Thus the subtle modifications that occur in patient reports when relayed from patient to physician to expert to literature text might inadvertently, but importantly, alter the original meaning. This problem is reduced if *verbatim* statements from patients can be adapted to inventory items.

The patient generation of items through focus groups, followed by individual patient interviews to establish item content and to clarify meaning, is increasingly becoming the standard practice.^[11] In both types of interviews, a professional interviewer leads the patient or patients through a detailed discussion of their experiences with the disease and/or their reaction to items. The interview is constructed to generate discussion that can be gleaned for potential items. These interviews should avoid any evaluation. Evaluation during patient interviews can inhibit discussion, especially of personal topics such as sexuality, and can therefore allow important, but sensitive, aspects of a disease to go undiscovered. Constituting groups with patients who have the desired characteristics of the instrument’s target population in common, but who are unfamiliar with one another, will also facilitate an open discussion.^[11] Transcripts of the interview are later reviewed and words and phrases that patients used to describe their experiences are identified for potential use as inventory items.

Patients typically provide a wealth of information concerning their disease or psychological state. For example, in the development of the PFSF, over 450 potential items were generated. Common statements heard from women suffering from hypoactive sexual desire were “I wanted to avoid sex” and “I felt sexually unattractive.” In addition, the amount of time spent on a certain set of symptoms by patients, or the emotion or degree of animation in the discussion can provide valuable clues as to the importance of various symptoms, feelings, attitudes, and emotions. A discussion of the degree to which a symptom or feeling has changed after the emergence of the disease can provide an important indication of its likely response to therapeutic interventions in the future.

Items should be reviewed for language level and items with an unusually high level should be eliminated or revised to an easier reading level; a common rule is that of a 6th grader or 12-year-old. Colloquialisms and slang terms should be eliminated unless absolutely needed for understanding.^[19] Compound items should be split into unitary items. For example, a compound item such as “I felt no

desire for sexual activity and could not become aroused” should be made into two unitary items “I felt no desire for sexual activity” and “I could not become aroused.” It may be beneficial to include items that express the same meaning with different terms to determine which will work best among the patients. A web-based tool, QUAID (<http://www.psyg.memphic.edu/quaid/html>) was developed by Graesser et al.^[20] to identify types of problems such as vague terms, complex syntax, or items with too high memory load.

Items that are extracted from the interviews are grouped together on the basis of content similarity in preliminary domains that are the precursors of the ultimate subscales of the final instrument. The domains should reflect any generally accepted medical criteria of the disease, as well as include concepts identified by patients even if these concepts are not generally recognized as important at the current time by medical or psychological science. Items that express different levels of the same feeling or symptom should also be included to provide a sufficient gradation along a continuum if the instrument is intended to measure response to a treatment. Foreexample, the three items “I was uninterested in sexual activity,” “I felt sexual desire,” and “I felt a high degree of sexual desire” represent a continuum of sexual desire. If each is measured using a six-point rating scale, a total score (after reversing item scoring for the negatively worded item) of 18 points represents a continuum along which a patient can express changes in sexual desire. IRT methods are discussed later but provide a more sophisticated method to assess “item difficulty”; a characteristic where more of a trait is needed in order for a person to respond in a positive direction. IRT models are being used to develop shortened instruments by selecting a set of questions whose “item difficulty” span the range of the underlying trait but are not redundant with one another.

In the development of the PFSF, the initial review was able to classify the 450 potential items obtained for the PFSF into 12 preliminary domains that seemed to be measuring distinct underlying constructs. Optimally, each domain will include enough items to result in the potential for reliable measurement of the underlying construct after item reduction by statistical techniques is completed (see the section “Quantitative Instrument Development”), but few enough

to avoid fatigue by those completing the inventory. The final review of the initial 450 items generated for the sexual function instrument resulted in 83 items arranged in seven domains, each containing from 5 to 19 items.

QUALITATIVE CONTENT VALIDATION

The objectives of the qualitative content validation are: to maximize the degree to which the items adequately represent the patients’ symptoms and experiences; to produce items that have clear, unitary, and unambiguous meanings; and, in the case of multilanguage inventories, to maintain similar meaning across translations. The Cognitive Interview Technique,^[21,22] or Cognitive Laboratory, is commonly used for qualitative validation. A cognitive interview is a one-on-one interview between a trained professional interviewer and a patient. The interviewer reviews the thought processes the patient went through in determining what the patient’s answer to each inventory item should be. In so doing, the patient reveals what the items mean to one’s self. Unlike item generation, the process is evaluative in nature and results in the elimination and/or the refinement of items.

In practice, a moderator asks the subject to read the instructions on the questionnaire and then to fill in responses. The subject is additionally requested to mark any words, phrases, or sections that were confusing or difficult to answer. The moderator then walks the subject through the questionnaire sentence by sentence and the subject describes one’s thought processes and understanding as the instructions are read and as the items are answered.

The cognitive interview process is an iterative one. Modifications resulting from earlier interviews are reviewed in subsequent interviews. The interviews identify items with multiple or ambiguous meanings, or meanings different from what the investigator intends. If the instrument is translated into languages beyond the original one, cognitive interviews serve to identify and to correct altered meanings resulting from the translation process. Such difficulties will occur even if items are carefully screened to avoid slang, colloquialisms, and inappropriately high language levels. [Table 1](#) includes examples of problematic

Table 1 Examples of Problematic Items and Domains

Item: “I feel like a sexual person”	After translation in French: “I feel like a prostitute”
Item: “I felt relaxed about sex”	Some patients reported feeling relaxed about the subject of sex but not about actually having sex
Item: “I felt apathetic about sex”	Patients did not know the meaning of the word “apathetic”
Item: “It took forever to get aroused”	Patients who did not have sex over the past month answered “never”
Domain: Spontaneity	Unintended meaning: Women with low libido reported that sexual activity was often spontaneous because they rarely thought about or planned for it
Anticipated meaning: A tendency of women with normal libido to engage in sexual activity with little or no planning	
Domain: Attractiveness	Ambiguous meaning: Patients were unclear as to whether the domain referred to how attractive they themselves felt, how attractive they found men, or if they felt men were attracted to them
Anticipated meaning: A measure of how attractive the patient felt	

items and domains identified by the cognitive interview process during the development of the PFSF.

While it is unlikely that ambiguity and unintended meaning can ever be reduced to zero, to the extent that this goal is achieved, the content of the instrument becomes increasingly valid for its intended purpose. The cognitive interview process ensures that an instrument measures what it is intended to measure and does so independently of its statistical properties.

QUANTITATIVE INSTRUMENT DEVELOPMENT

The third step in this approach uses psychometric item reduction and multivariate analysis techniques to identify the underlying factors that describe the characteristics of the disease that are meaningful to the patients and to determine the subset of items that reliably measures each factor (i.e. the measurement model). The processes are executed among patients drawn from the same population as those who generated and reviewed the items and domains, and are the target population for use with the instrument. These methods are widely discussed in the psychometric literature.^[9,11,23–25]

METHODS OF ANALYSIS

Developing a good scale involves selecting items that are good indicators of factors and ensuring factors are well-measured (i.e. developing a good measurement model). Although many steps have been incorporated along the way to provide items that will perform well, there still may be issues.

Hence, we've broken this process into two sets of analyses: (i) analyses to reduce the number of items in the instrument by eliminating those with poor data quality; and (ii) analyses to identify a good measurement model. Although these analyses are discussed in a sequential fashion, in practice, the process is iterative, with later analyses sometimes necessitating a review of decisions based on earlier results. Additionally, although items performing poorly may warrant immediate elimination, for others, decisions as to whether or not to retain the item may hinge on the combined results of multiple analyses as well as criteria involving clinical considerations.

DATA QUALITY

Missing data rates and item frequency distributions are examined to identify problematic items. High missing data rates on an item may indicate that the item was not understandable or relevant. If the inventory deals with a sensitive subject, for example, items with high missing data rates may represent a topic that patients do not feel comfortable

responding to, perhaps because the item is viewed as too personal or intrusive. A lack of understanding of the item may be another reason for high missing data rates. Additionally, overall high missing data rates may indicate patient fatigue, which could indicate an overly lengthy instrument.

Items with high “endorsement frequency”^[23] (i.e., items having a high percentage of subjects with floor or ceiling responses or one particular response, e.g. exceeding 80%) should be considered for elimination. Assuming that a high response to a particular item indicates a lack of that aspect of the disease, subjects scoring at the highest response level would not be able to move in a more positive direction with respect to that item after treatment. Therefore retention of that item may reduce the sensitivity of the instrument to clinical intervention. For example, 48% of the patients responded either “seldom” or “never” to the phrase “I feel sexually unattractive” and hence this item was deleted.

Items having a large proportion of subjects with floor responses or one particular response may also warrant elimination. Although a subject scoring at the lowest response would have a large potential for improvement, a high percentage of subjects with that response may indicate that the item difficulty level is such that movement to the next response would take an inordinate amount of change, again reducing the sensitivity of the instrument to detect therapeutic changes in the positive direction. A typical sample of patients represents various degrees of the severity of the disease. Sets of items that adequately describe a range of disease levels will likewise allow patients' responses to more accurately describe their particular level of the disease, and to reflect movement indicating either an improvement or a worsening of their condition.

Other methods are discussed by Juniper et al.^[10] They suggest eliminating items based on a composite score, termed “impact,” consisting of the proportion of patients in a sample experiencing an item multiplied by the mean rating of importance. Items having a low “impact score” are deleted. For example, items that are experienced by a large proportion of patients but have low importance would be eliminated from the instrument. Another method they suggest is to eliminate items not changing with known changes in the disease state or after treatment with a known effective therapy. This depends upon an effective therapy already existing for the condition or a disease state of relatively short duration with a clear onset and a known duration.

DETERMINATION OF FACTOR STRUCTURE

One approach to determine domains is to use judgment based on clinical experience or scientific knowledge, or domains in already established instruments. Each of these

approaches has its legitimate use, especially if a theory in the area is developed enough to feel confident with these decisions. However, the scientific and medical conceptualization of disease states evolves and changes over time, as does the patients' conceptualizations and ways of expressing what is important.^[11] Even individual words and items can change in meaning or relevance. All of these factors can contribute to the invalidity of an instrument or item. Neither factor analysis (discussed below) nor scientific and clinical considerations alone can adequately guard against this difficulty. Typically, both are useful to develop a sound measurement tool, which is patient-relevant and reflects state-of-the-art science.

Instruments typically are developed so that the items within a domain are homogeneous. In other words, they each measure some facets of the same underlying construct. Streiner and Norman^[24] note that without this property, a domain may be tapping a number of traits. Consequently, the exact effect of treatment will be indeterminate. Analyses that establish scale homogeneity are discussed here.

Factor analytic methods can be used to assess the underlying dimensionality of a set of items and to identify groups of related items that are hypothesized to measure unitary underlying constructs. In practice, the constructs are referred to as factors or domains. The factor analysis model expresses a set of items as a continuous function of factors and residuals. Exploratory factor analyses is an exploratory procedure which does not pose any constraints on the relationship between the items and the factors but only restricts the number of factors. Confirmatory factor analysis will be discussed below where constraints are placed on this relationship; forcing items to relate to particular factors. A nice overview of EFA and CFA as well as a potential strategy for instrument development is given by Muthen and Muthen in their Mplus short course notes, Topics 1 (continuous outcome variables) and 2 (categorical outcome variables).^[26]

Initially, a principal components analysis is run in order to determine if all items, or which items, relate to a single general factor. The first component of an unrotated principal components analysis identifies those items that tend to share a common underlying attribute or construct in the dataset. In the case of the PFSF, items should revolve around sexuality. Items that do not have a meaningful correlation (e.g., correlates less than 0.4) with the first unrotated principal component are removed. Inventories will frequently incorporate both positively and negatively worded items as a means of countering acquiescent responding,^[23,25,27,28] in which patients show a tendency to agree with all items regardless of content. In that case, it is possible that positive and negative items will distribute across the first two principal components, with one component containing positively worded items and the other containing negatively worded items, even though both measure the same underlying general construct. In

that case, items correlating with the first two unrotated principal components should be retained.

Principal components analysis is followed by a rotated factor analysis using (e.g., a varimax and/or oblique rotation). This analysis is done to identify factors (i.e., linear combinations of items) that account for distinct portions of the variability in the overall data set. A scree plot of the eigenvalues—a measure of the amount of variability extracted by a factor, corresponding to each factor, by a factor number—can be used to aid in determining the number of factors to be rotated. One option, commonly used, is to base the decision on the number of factors with eigenvalues greater than 1. The justification for this is that any factor retained must contribute more than the total variance added by a single variable. A discussion of this topic as well as other methods of factor analysis can be found in Comrey and Lee.^[29]

Items that correlate highly with a given factor are said to load on that factor and can be viewed as a measurement scale for the underlying construct represented by the factor. Items showing complex correlations across multiple dimensions (i.e., loading on numerous factors) or items having small loadings across all dimensions (e.g., factor loadings <0.4 on all factors) should be eliminated from the instrument.

A portion of the factor analysis table from the factor analysis performed on the PFSF is given in [Table 2](#). Items and domains have been selected for illustrative purposes and do not represent the entire factor analysis table. The first four items show unique loadings on the second factor, later to be labeled “Sexual Desire,” and illustrate a pattern of factor loadings indicating that the items are all primarily measuring the same underlying factor. Certain items considered originally to be capturing separate domains of arousal and orgasm were found to load on the same factor (Factor 4). As will be discussed later, two domains, “Sexual Arousal” and “Orgasm,” were later constructed based on clinical perspective. Lastly, for a number of items in the original Pleasure domain, unique loadings on the first factor were obtained. However, the item “It was very easy to have sex” was deleted from the instrument because of relatively low and multiple factor loadings, suggesting some degree of ambiguity. The second item, “Having sex was a chore,” although initially thought to represent “Sexual Pleasure,” was later found to load to a greater extent on the “Sexual Responsiveness” domain and was therefore moved to this domain.

In parallel to the above analyses, item-total correlations can be used to build and confirm scale homogeneity, as well as changes in internal consistency as individual items are removed. As further discussed in “Instrument Validation” below, these properties are important in establishing scale homogeneity. The item-total correlation measures the correlation between an item and its domain total score and is assumed to reflect the extent to which the item measures the same underlying construct as do the other items in the

Table 2 Example of a Rotated Factor Analysis

Original domain item	Factor 1: Pleasure	Factor 2: Desire	Factor 3: Responsiveness	Factor 4: Arousal/orgasm
<i>Desire</i>				
I felt sexual desire	0.25	0.73	0.14	0.07
Desire item 2	0.22	0.73	0.37	0.01
Desire item 3	0.20	0.76	0.29	0.12
Desire item 4	0.21	0.74	0.18	0.18
<i>Arousal</i>				
It was very difficult for me to become aroused	0.29	0.46	0.14	0.66
Arousal item 2	0.24	0.37	0.26	0.61
Arousal item 3	0.25	0.24	0.30	0.65
<i>Orgasm</i>				
It took a lot of work for me to reach orgasm	0.27	−0.01	0.05	0.84
Orgasm item 2	0.32	0.11	0.03	0.83
Orgasm item 3	0.44	0.26	−0.07	0.62
<i>Pleasure</i>				
It was very easy to have sex	0.40	0.26	0.48	0.16
Having sex was a chore	0.21	0.15	0.74	0.12

domain. The item-total correlation is corrected for overlap by removing that item from the sum of the other items when computing the domain score. Items not correlating significantly with their own domain total (e.g., item-total correlation corrected for overlap <0.4) are considered for elimination. Additionally, items correlating more with the total domain score of another domain should be eliminated or moved to the other domain. The principle behind this analysis is similar to that of the principal component and rotated factor analysis and provides complementary results.

Another approach, which can be used to build scale homogeneity, is to consider changes in the reliability (e.g., Cronbach's α) of the domain as it is computed with and without each item.^[24] If a significant increase in reliability is noted when a particular item is excluded, then that item should be eliminated.

The determination of domains can, and often must, be done in conjunction with nonstatistical considerations. For example, as shown in Table 2, factor analyses done on the PFSF items found that those appearing to measure sexual arousal and those measuring orgasm loaded on a single factor. Sexual arousal and orgasm are viewed by patients as separate entities. Further, the DSM-IV5 lists arousal and orgasm disorders as distinct diseases. These considerations made separating the two sets of items into two inventory domains very reasonable.

The construction of domains by the use of factor analysis and item-total correlations will result in homogeneous or nearly homogeneous domains. As mentioned earlier, the more similar the items are to each other, the more likely they are to measure the same construct. However, as items become increasingly similar, they are also more likely to measure

the same facet of the underlying construct. Such items add little to the domain, and high degrees of redundancy may decrease the content validity of the domain. Factor analysis and item-total correlations do not address this issue. Redundant items within a domain can be identified by inter-item correlations. As a rule of thumb, items that correlate highly (e.g., interitem correlation >0.75) are considered redundant. Redundant items can also influence the results of the factor analyses, leading to trivial factors or bloated specific factors. Hence looking at inter-item correlations both before and after the factor analysis is useful.

CONFIRMATORY FACTOR ANALYSIS

Once the final measurement model is identified, CFA methods can be used to assess whether the factor model established above fits a new sample from the same population or potentially to investigate its fit in a new population. Brown et al.^[30] provides an in-depth discussion of CFA modeling and its advantages over EFA modeling.

The final PFSF included 37 items allocated to seven domains; Sexual Desire (9 items), Sexual Arousal (3 items), Sexual Self-image (4 items), Orgasm (4 items), Sexual Concerns (3 items), Sexual Pleasure (7 items), and Sexual Responsiveness (7 items).^[7,8]

A 7-factor CFA model was fit in Mplus using an independent sample of data from 2 large phase III clinical studies to assess the efficacy and safety of a testosterone patch versus placebo on Sexual Desire and other aspects of sexual functioning.^[31,32] The majority of study patients were from the United States ($n = 1020$ of 1094 subjects)

and hence initial interest was to confirm the factor structure in this set of patients.

To assess the fit of the model the comparative fit index (CFI) and Tucker Lewis index (TLI) were used with values above 0.9 indicating an acceptable fit.^[33,34] The root-mean-square error of approximation (RMSEA) and Standardized Root Mean Square Residual (SRMR) were also examined with values less than 0.08 considered acceptable.^[35]

The CFA model produced a significant chi-square value (chi-square = 3403, df = 608, $p < 0.0001$). Marsh and Hau^[36] suggest using the Chi/df index over the Chi-square alone. Values less than 5 indicate reasonable fit while values between 2 and 3 indicate good fit. In this case, the Chi/df was slightly greater than 5, with a value of 5.5.

Values of 0.90 and 0.89 were observed for CFI and TLI, respectively. The RMSEA was 0.069 with 90% CI: (0.067, 0.071) and SRMR was 0.071. All factor loadings were highly statistically significant. Hence the data fit a seven-factor CFA reasonably well.

Even though an acceptable fit was observed, further examination for the purpose of illustration was performed. Examination of the modification indices (measure of change in chi-square associated with freeing the value of the parameter) indicated the possibility that item 4 on the Sexual Self-Image scale (“Unhappy about yourself sexually”) may cross-load with the Sexual Concerns domain as well as the potential for some method effects (e.g. due to positive and negative wording of items). For example, items 5 (“I lacked sexual desire”) and 7 (“I was uninterested in sex”) of the Sexual Desire domain had a large modification index indicating correlated residuals. In this case, these two items were negatively balanced while the remaining questions for that domain were positively balanced. The ability to model correlated residuals and hence address method effects is one of the major advantages discussed by Brown^[30] of CFA over EFA.

A model was fit where item 4 of the Sexual Self-Image scale was eliminated and 8 pairs of error terms were allowed to co-vary. In this case, the minimum criteria for acceptance were observed for all the fit indices.

The above analyses treat the response scale as continuous. However, the items in the PFSF utilized a 6-point Likert scale ranging from 1 for Always to 6 for Never (high score associated with high sexual functioning). In this case, categorical EFA and CFA models are more appropriate. Categorical EFA and CFA models can be run in Mplus.^[26] Polychoric correlation matrices are used rather than Pearson correlation matrices for categorical EFA. 2-parameter logistic or normal ogive IRT models are utilized to model the probability of a particular response given a person's underlying latent trait value.

Analyses on the data above were repeated treating the items as 4-point categorical variables where response options 4, 5, 6 (e.g. “I lacked sexual desire” responses of “sometimes”, “seldom”, or “never”) were collapsed due to very few patients with those responses. In this case, similar

results were seen as those discussed above with continuous data again suggesting reasonable fit to a 7-factor model.

Muthen and Muthen^[26] indicate that treating the data as categorical has less to do with the number of response categories but rather the presence of floor and ceiling effects. Treating the variables as continuous can lead to attenuated correlations and factors that reflect item difficulty extremeness.

ITEM RESPONSE THEORY

The value of eliminating redundant items and of including items with varying degrees of difficulty have been discussed previously. A tool that allows assessment of these characteristics for a set of items is item response theory (IRT).

Item response theory (IRT) models are mathematical functions relating the level of an individual's latent trait with the probability of observing a particular response. Hays et al.^[37] provide a nice overview of IRT basics, common models, advantages provided by IRT models, as well as challenges in applying IRT methods. For IRT models, unidimensionality is assumed. Because this may not hold strictly, analyses to assess whether the scale is “essentially” unidimensional have been considered.^[17,38]

Figure 1 below shows the Item Characteristic Curve (ICC) for items 1, 3 and 8 of the Sexual Desire domain based on a 1-dimensional CFA of all 9 items. The probability of endorsement, in this case, responding “Sometimes,” “Often,” “Very Often,” or “Always” (e.g. item 1 “I felt like having sex”) for a given level of Sexual Desire is plotted for each item based on a 2-parameter logistic model.

In this model there are 2 parameters of interest. The discrimination parameter (slope of the ICC curve) considers the change in probability associated with changes in the level of the underlying trait. Items with higher discrimination will have steeper slopes. In this example, item 8 (“I got warm all over just thinking about sex”) discriminates less than questions 1 and 3.

Fig. 1 Item Characteristic Curves corresponding to items 1, 3, and 8. Probability corresponds to the probability of responding “Sometimes”, “Often”, “Very Often”, or “Always” (e.g. item 1 “I felt like having sex”) for a given level of Sexual Desire

Fig. 2 Item Characteristic Curves for all 9 Sexual Desire Items. For positive balanced items (1–4, 6, 8–9) the y-axis corresponds to the probability of responding “Sometimes”, “Often”, “Very Often”, or “Always” (e.g. item 1 “I felt like having sex”) for a given level of Sexual Desire. For negative balanced items (5 and 7) the y-axis corresponds to the probability of responding “Never”, “Seldom”, “Sometimes”, or “Often” (e.g. item 5 “I lacked sexual desire”) for a given level of Sexual Desire

The second parameter is the difficulty parameter and corresponds to the value of the latent trait at which the probability of endorsement is 50%. In this case, item 8 is the most “difficult” item since it takes more of the latent trait, i.e. Sexual Desire, for it to be endorsed, while 1 is the easiest since it takes less of the latent trait to be endorsed.

Figure 2 illustrates the ICC for all 9 items of the Sexual Desire domain. In this case, one can see that for some items, e.g. items 4 and 5, 3 and 6, and 2 and 9, similar discriminations and difficulties in measuring Sexual Desire are obtained.

Although not discussed here, an extension of the 2-parameter logistic model for ordered categorical variables is given by the graded response model. In this case, each item is described by one slope parameter and $k-1$ between category threshold parameters where k refers to the number of response categories.^[37]

Evaluating the discrimination and difficulty parameters can provide information to allow for shorter yet reliable scales to be assembled. Numerous other uses for IRT models in scale construction, such as test equating, assessment of appropriateness of response options, or assessing differential item bias to name a few, can be found in the articles already referenced.

SCORING

A common algorithm for summarizing domain and inventory data is to compute a simple average or sum of the items in the domain. A second possibility is the weighted average of the items in the domain where the weights are the factor loadings from the factor analysis. Unless the factor analysis producing the weights is based on a very large sample, these estimates may be unreliable and specific to the sample from which they were derived. Other possible weights include item-total or item-criterion

correlations, but these correlations, like factor loadings, can vary from study to study because of sampling error. The differential weighting of items generally adds little value in terms of increased reliability beyond what the number and the quality of items provide [9]. A simple average with unit weight is therefore usually appropriate. In the case of missing responses to items, a common approach is to impute the average of the nonmissing items for the missing items, in a domain, prior to computing the score.

INSTRUMENT VALIDATION

After the items and domains have been identified, the psychometric properties of the instrument are assessed to determine if the instrument meets established criteria of reliability and validity. While the major indices of reliability and validity can be computed on the data collected during the item reduction process, such calculations may overestimate the true value as similar analyses may have been used to develop the instrument. To demonstrate the generalizability of the instrument beyond the data from which it was generated, the inventory must be tested among an independent sample of patients drawn from the same target population.

One method to obtain an independent dataset is to withhold a subsample of data from patients in the initial development and item reduction analyses and later use this sample to examine the properties of the reduced instrument. However, this procedure may be influenced by the fact that the withheld data that are later analyzed for psychometric properties consist of item responses collected in the context of the unreduced instrument, thereby allowing the possibility of context effects.^[21] Therefore the use of an independent study to establish instrument properties is the preferred approach.

Psychometric properties considered necessary for a valid and reliable instrument include good test-retest reliability and internal consistency, and good content, concurrent, and construct validity. The assessment of an instrument’s validity is an ongoing process in which hypotheses regarding the constructs measured by the instrument are repeatedly generated and tested. It is this accumulation of evidence, supporting the instrument’s usefulness as a measurement tool of the intended disease state, which establishes its validity. Definitions for validity and reliability can be found in numerous texts.^[9,23–25]

VALIDITY

Validity refers to the property of measuring what is intended to be measured. Three forms of validity that are part of a validated instrument are content, concurrent, and

construct validity. Content validity refers to the adequate sampling and presentation of relevant disease characteristics. This form of validity was discussed in earlier sections concerning qualitative validation and therefore will not be further discussed in this section.

CONCURRENT VALIDITY

Concurrent validity is established for a new instrument by demonstrating a good correlation with an already existing tool that is widely accepted as measuring the same construct(s). For example, a clinical evaluation by a physician might be considered the “gold standard” diagnosis. Or a well-recognized and accepted diagnostic criterion that is widely used by practitioners in the area may exist. In the case that the existing tool is continuous, a Pearson or Spearman’s correlation coefficient can be computed.^[39] In the case of a dichotomous diagnostic tool, the area under the Receiver Operating Characteristics curve^[40] can be used to establish a good relationship.

If no such “gold standard” exists, one option is to compare the new instrument to existing instruments that measure similar or related constructs. This is referred to as convergent validity and is a form of construct validity (discussed below). For example, all instruments in the same general area of sexual function should show some degree of relationship. Furthermore, all instruments or domains designed to measure sexual desire should show a somewhat closer relationship to one another than they do to other domains of sexuality, even if they have been developed on varying populations.

An example of convergent validity is shown in [Table 3](#). These data show the relationship between data on the domains of the PFSF and the Derogatis Interview for Sexual Function-Self Report© (DISF-SR21). The DISF-SR is a gender-keyed brief outcome measure to assess general sexual functions. The instrument measures five domains of sexual function: sexual cognition and fantasy, sexual arousal, sexual behavior and experiences, orgasm, and

sexual drive and relationship.^[41] Correlations of domains that were expected prospectively to be strongly related are shown in bold print. The overall pattern of correlations in this table is supportive of the convergent validity of the PFSF.

CONSTRUCT VALIDITY

Construct validity is the extent to which an instrument or its domains measure the underlying constructs they are purported to represent. One way to examine construct validity is to determine if the data collected by the instrument reflect hypotheses generated by a consideration of the underlying constructs. To the extent that hypotheses are developed and supported by the instrument, the instrument’s construct validity is accrued.

One form of construct validity is referred to as “known groups validity” or discriminant validity. It refers to the instrument’s ability to detect differences between groups “known” or expected to differ. For example, the PFSF is purported to characterize the subjective sexual feelings and symptoms of women with HSDD. Women diagnosed with HSDD are therefore expected to score lower on the domains of the PFSF than women with normal libido. [Fig. 3](#) shows the mean responses on the domains of the PFSF from the three original validation studies conducted in the United States, Canada, Europe, and Australia (data on file). A repeated-measures analysis of covariance showed that women with HSDD scored significantly lower than normal women in all regions studied ($p < 0.001$). Of note also is the similarity of profiles for the three general regions studied, hence supporting the expectation from the qualitative content validation that the same content would be captured over various regions.

Similar to convergent validity discussed above, divergent validity can additionally be used to establish construct validity. Just as one would expect two measures assessing the same construct to be moderately or strongly related,

Table 3 Correlation of the PFSF with the DISF-SR

PFSF domain	DISF-SR domain				
	Sexual cognition/ fantasy	Sexual arousal	Sexual behavior/ experiences	Orgasm	Drive and relationship
Sexual desire	0.64	0.76	0.67	0.69	0.82
Arousal	0.49	0.70	0.56	0.80	0.82
Orgasm	0.47	0.66	0.47	0.87	0.70
Sexual pleasure	0.51	0.73	0.56	0.83	0.81
Sexual concerns	0.45	0.67	0.55	0.74	0.78
Sexual responsiveness	0.50	0.67	0.63	0.66	0.79
Sexual self-image	0.46	0.66	0.60	0.66	0.73

PFSF, Profile of Female Sexual Function; DISF-SR, Derogatis Interview for Sexual Function—Self-Report.

Fig. 3 The PFSF—discrimination by domain across geographies. EU = Europe/Australia; US = United States; Cn = Canada

one would expect measures that are conceptually independent to be unrelated, or only weakly related. The establishment of low correlations between independent measures is known as divergent validity. For example, Rosen et al.^[42] established divergent validity for the International Index of Erectile Function (IIEF) by showing low correlations of the IIEF with the Locke-Wallace Index of Marital Satisfaction Scale. The observed lack of relationship provides confidence that the IIEF measures erectile function and not some aspect of marital adjustment.

Convergent and divergent validity were discussed above relative to the domain level. Additionally, convergent and divergent validity can be established at the item level through the use of item-total correlations. An instrument has good convergent and divergent validity if items correlate to a greater extent with their own domain than with the other domains. Multitrait/Multi-item Analysis Program—Revised (MAP-R)^[43] computes the percentage of correlations in which an item correlates significantly more with its own domain than with other domains and classifies an instrument as having achieved “scaling success” if this occurs for at least 80% of the item-total correlations within each domain and overall.

For instruments that are intended for use in clinical trials with drug therapy, an important form of construct validity is responsiveness to change or sensitivity to the effects of treatment. As discussed in “Quantitative Instrument Development,” the responsiveness of an item to change can be a vital aspect of instrument development. Rosen et al.^[42] demonstrated the IIEF to be sensitive and specific to changes after treatment by showing statistically significant changes from baseline in domain scores for a

subgroup of subjects self-rated as responders while no statistically significant changes were found for the subgroup of subjects self-rated as nonresponders.

TEST-RETEST RELIABILITY AND INTERNAL CONSISTENCY

Reliability refers to the reproducibility of a measure on separate measurement occasions. Ideally, an individual's score on a measurement tool will remain constant over time if no intervention or other relevant event that might be expected to affect measurement outcome occurs. Scores on successive testing can be affected in several ways. For example, a true change in the underlying condition can occur with treatment, or spontaneously in the absence of treatment. Alternatively, a change in a patient's score might occur spuriously as a result of prior exposure to the instrument. The demonstration of test-retest reliability provides the investigator with increased assurance that any changes in scores from one testing to the next are the result of a true change in the underlying disease and are not a spurious result related to repeat testing.

An intraclass correlation coefficient (ICC) corresponding to a one-way random effects model, $\rho = [(\sigma_s^2)/(\sigma_e^2 + \sigma_s^2)]$, can be used to estimate test-retest reliability. This coefficient represents the correlation between two responses from the same individual. Shrout and Fleiss^[44] discuss other models for estimating ICC and give the assumptions underlying these models. Bartko^[45] compares these approaches and shows that the ICC from a one-way random effects model is the most conservative. Alternatively, a Pearson correlation coefficient can be used to estimate test-retest reliability. However, this estimate is less conservative than ICC in that a constant change between repeated sampling of the patients can lead to a large Pearson correlation even when subjects' responses have not remained constant.

Another form of reliability can be estimated by Cronbach's α coefficient. Cronbach's α coefficient estimates the internal consistency or scale homogeneity of a domain. It is a function of the number of items in a domain and the average interitem correlation. Cronbach's α values between 0.75 and 0.94 are desirable for population-based instruments, and values at or above 0.95 are desirable for instruments to be used for measurement or diagnosis with individuals.^[46]

Table 4 illustrates test-retest reliability and internal consistency estimates for the PFSF from an independent confirmatory validation study involving menopausal, low-libido women and age-matched, normal-libido controls. The ICCs indicate consistent responses across a 4-week time interval. Additionally, Cronbach's α values indicate good domain homogeneity for all the domains.

Table 4 Test-Retest Reliability and Internal Consistency of the PFSF

Domain	Test-retest reliability		Internal consistency	
	Low libido	Normal libido	Low libido	Normal libido
Sexual desire	0.73	0.76	0.91	0.93
Arousal	0.63	0.68	0.92	0.81
Orgasm	0.75	0.82	0.92	0.88
Sexual pleasure	0.76	0.80	0.95	0.93
Sexual concerns	0.58	0.74	0.86	0.74
Sexual responsiveness	0.83	0.91	0.92	0.89
Sexual self-image	0.65	0.78	0.83	0.85

CONCLUSION

The development and the validation of psychometric instruments require both qualitative and quantitative methods to optimize content validity and to establish acceptable psychometric and statistical properties. A comprehensive approach to achieve this objective was discussed in this article. The approach to instrument development discussed in this article consists of three major steps: (i) preliminary item and domain generation; (ii) qualitative content validation; and (iii) quantitative item reduction analyses. The incorporation of the methods discussed in the first two steps, in particular the cognitive interview process, is important to achieve a complete sampling of the important characteristics of the disease, adequate patient understanding, and the robustness to language variation. The quantitative methods are designed to identify sensitive items that are capable of providing good-quality data and stable data and domains that measure known unique aspects of the disease. These properties enhance the ability of the instrument to determine the exact effects of treatment.

The validation of an instrument requires a demonstration of acceptable reliability and validity characteristics. Standard analyses for establishing and assessing reliability and validity were given in this article.

ACKNOWLEDGMENTS

We would like to acknowledge Dr. Colleen McHorney, Dr. Leonard Derogatis, Dr. John Rust, and Dr. Susan Golombok for their contributions to the development of the PFSF and their direction in determining the appropriate methodology.

Integrated Summary Report

Laura J. Meyerson

Biogen, Inc., Cambridge, Massachusetts, U.S.A.

Abstract

An integrated summary report is a compilation of all the evidence for efficacy and safety from the data collected in all completed clinical trials. This entry breaks down each individual component of the integrated summary report.

INTRODUCTION

There are many reasons to integrate and to summarize all the data from a clinical trial program. Each clinical trial in the program is unique in its objective and design. Some are small safety studies among normal volunteers, while others are efficacy trials in a large patient population. The primary reason to create an integrated summary is to compare and to contrast all the various study results and to arrive at one consolidated review of the benefit/risk profile. A second and important reason is to reach a defensible statistical conclusion, through an exploration of the integrated data, that no competing alternative hypothesis that can reasonably account for the observed findings exists. Third, pooling the data from various studies enables the examination of trends in rare subgroups of patients, such as the elderly, those with differing disease states (mild vs. severe), and those with comorbidities at baseline. Last, providing such a summary in the new drug application is required by the Food and Drug Administration (FDA) and other international authorities.

OVERVIEW

An integrated summary report is a compilation of all the evidence for efficacy and safety from the data collected in all completed clinical trials. There are two integrated summary reports: the integrated summary of efficacy (ISE) and the integrated summary of safety (ISS). Both are required for all new drug applications in the United States.

The analysis approach for the ISE is substantially different from that for the ISS. The ISS summarizes all data collected from the clinical trial program, including normal volunteers and patients. The ISE includes data only from those clinical trials that present some evidence of efficacy, either through surrogate markers or through well-designed tests for efficacy. The ISE requires a more prospective approach to analysis, whereas the ISS approach is more sensitive because it allows a retrospective search through

all the data to expose possibly rare but important side effects. As a result, pooling data across studies is required in the ISS to obtain more reliable estimates of the incidence of rare adverse events. A pooled analysis in the ISE is not required, but it can be useful for estimating a more precise treatment effect. However, pooling is generally not useful for substantiating evidence of efficacy, without side-by-side study results each showing evidence of efficacy separately. Therefore this entry has two sections. The first section is devoted to the ISE, the second pertains to the ISS.

There are a number of areas of specific interest that arise within the integrated summary report. A description of the demographic and baseline clinical features of the population treated during the course of the clinical trial program is necessary. Key questions concerning efficacy need to be addressed by considering the results of relevant trials and by highlighting the degree to which they reinforce or contradict each other. For example, when is it useful to pool trials to obtain a more precise estimate of the treatment effect? All the safety information available from the entire database of all studies should be summarized. How can the data be thoroughly searched so that any potential safety concern is identified?^[1]

INTEGRATED SUMMARY OF EFFICACY

Dose Rationale

One of the most important sections of the ISE is that on dose selection. Efficacy information at all doses studied should be analyzed in such a way that a dose or dosing interval can be recommended. Information that is needed to support a new drug application should identify an appropriate starting dose, as well as how to adjust dosage to the needs of a particular patient.^[1] The maximum dosage beyond which there is no likely benefit or that would produce unacceptable side effects should also be identified. It is important to identify the lowest dose exhibiting a clinically important effect. To know for certain that one has identified the minimally

effective dose, it is often necessary to study a dose that has no clinical benefit compared to placebo. This section of the ISE should contain the information from the dose response studies, that is, controlled information on the minimum, maximum, and average dose from the response curve for efficacy. It should also contain any other information from other doses. Safety needs to be brought into the discussion because choosing the dose is always a risk/benefit decision.

In order to provide proper dose–response information, there should be at least one prospective dose–response study in the ISE that explores more than three doses. In principle, being able to detect a statistically significant difference using pairwise comparisons between doses is not necessary in such a trial, if a statistically significant trend (upward slope) across doses can be established using all doses. The more doses explored in this study, the better the dose–response curve will be characterized. It should be demonstrated, however, that the dose to be recommended has a statistically significant and clinically meaningful effect. This can be done in the dose–response trials or in other adequate and well-controlled trials.

The entire database should be examined extensively for possible dose–response effects. Limitations of study design should be considered. For example, the titration scheme designs should not be pooled with fixed-dose designs. Many trials will titrate to the desired response. Weaker responders would then receive the higher doses. This may lead to an inverted U-shaped dose–response curve. Despite the different designs, all clinical data should be examined for dose–response information.

The entire database should be examined to explore possible differences in subgroups of patients based on baseline differences. Age, gender, and race should always be examined. Other important covariates may be baseline disease severity and baseline comorbidities. Height, weight, renal function, and lean body mass are important in looking at the dose–response data as a function of body size and metabolism.

Efficacy Data

The International Conference on Harmonization guideline^[2] says that individual clinical trials to demonstrate

efficacy must be performed and must be large enough to satisfy their objectives. Additional valuable information may also be gained by summarizing a series of clinical trials that address essentially identical key efficacy questions. This can be done in the ISE. The main results of such a set of studies should be presented in an identical form to permit comparison across studies, focusing on estimates plus confidence limits. The use of meta-analysis to combine these estimates of treatment effect across studies of the same dose regimen is often useful because it allows a more precise overall estimate of the treatment effect at those doses. However, only under exceptional circumstances would a meta-analysis be the most appropriate way to demonstrate efficacy via an overall hypothesis test.

Figure 1 shows the clinical trials that are summarized in the ISE. In this program, phase IIB and phase III studies are the focus of the ISE. These studies should be planned while taking into account that they will be combined and presented together for an overall estimate of the benefit of the therapy. They should have similar endpoints (primary and secondary), similar populations, and some overlap in the dose regimens. Phase IIB is the study that demonstrates “proof of principle,” usually through a statistically significant increase in efficacy with an increase in dose. There should be two Phase III studies—one to demonstrate a statistically significant and clinically meaningful benefit, and the other to replicate that demonstration.

Meta-Analysis

In pharmaceutical development, it is known at the time of positive Phase II results that a new drug application is likely to be filed. It is at this time that the researchers should start planning for the ISE. In the planning of the adequate and well-controlled trials, one should incorporate any needs that the ISE plan may require. It is at this time that the decision to do meta-analyses should be made in a prospective manner. The individual studies can then be designed with pooling as a goal. Which studies will be pooled and which studies will not can be decided prior to obtaining the results. Then pooling will not be influenced by the

Fig. 1 The integration of efficacy information to support a marketing application

results. The decision to undertake a meta-analysis after the data from all the efficacy studies have been reviewed cannot be made to save any negative or borderline results that were obtained in the individual studies. In such a case, the researchers could pick and choose studies so that the results favor the treatment being proposed. A simple principle is to perform a meta-analysis in a manner that is consistent with the conduct of a single well-designed randomized clinical trial.^[3]

Flather et al.^[4] address why we do meta-analysis: “Even large randomized clinical trials may not answer specific questions reliably because of weaknesses in their design or, more commonly, because they are not large enough to detect the moderate but medically important treatment effects that can be expected realistically.” The primary reason for performing meta-analysis is to obtain more reliable estimates of the treatment effects. Secondary reasons for performing meta-analysis are (1) to summarize formally the available information on a particular treatment, and (2) to generate hypotheses that may be tested in future trials. For example, in the development of a treatment for ischemic stroke, each individual study could be powered for functional status, while the meta-analysis could be powered for mortality (which would generally take larger numbers). In this case, the randomized controlled trials are powered for differences in endpoints that are more sensitive (possibly, surrogates), while meta-analysis is powered for the less sensitive clinical endpoints. The pooling may allow the detection of clinically significant changes on clinical endpoints because of the increase in sample size. This is similar to the optimal information size discussed in Pogue and Yusuf.^[5]

In pooled analysis, all appropriate clinical trials should be included to avoid bias. Studies should be excluded if not of a consistent, similar design eligibility criteria, trial treatment regimens, concomitant medications, definitions of outcome events, or length of follow-up. Studies with incongruent results should not be pooled but should be examined for an explanation of their differences. Given the retrospective nature of most meta-analyses and the multiple comparisons that are carried out, many researchers believe that a *p* value of 0.05 is not stringent enough. Levels of 0.01 or even 0.001 should be routinely considered.^[6]

After the decision to do phase III studies, develop a prospective protocol for your meta-analysis by defining specific hypotheses (primary and secondary) to be tested:

Frame a question that is medically relevant and biologically sensible.

Define the study population and relevant subgroups.

Define treatment regimens to be included.

Define outcomes of interest.

Identify trials that will be pooled in a prospective manner.

Use only properly randomized trials.

Include all patients randomized in each trial.

Prespecify valid statistical methods to combine data.

Determine the primary endpoint as well as the effect size necessary to be clinically meaningful.

The ISE should have a description of the entire efficacy database’s demographics and baseline disease characteristics. Subgroup analyses for age, race, gender, and other characteristics should be looked at by pooling data over different studies of the same dose regimen. The intent-to-treat population should be the focus; however, if there is a large number of discontinued patients or major protocol violators, the results from a “clean” subpopulation, valuable for efficacy, should be presented as well.

The pooled results should always be presented in combination with the individual study results. This allows the examination of the degree of heterogeneity between the studies.^[7]

INTEGRATED SUMMARY OF SAFETY

The summary of safety data is an important and very large part of a new drug application. It is important to investigate the safety data thoroughly through pooling to search for rare adverse events. For example, if an adverse event rate is truly only 1%, then more than 300 patients are needed to observe it with 95% confidence. This is from “the rule of three,” which states: If none of *n* patients shows the event of interest, then the upper 95% confidence limit is approximately $3/n$. So if the event were truly rare, say 0.01%, then 30,000 patients would have to be observed, which is larger than most randomized clinical trials. It is also important to estimate accurately the expected rate of any common adverse event associated with the use of the drug.

The International Conference on Harmonization guideline^[2] states that all safety data need to be examined thoroughly to uncover any indications of potential toxicity, and to follow up any indications by searching for an associated supportive pattern of observations. The combination of the safety data from all human exposures to a drug should provide the main source of information, because its larger sample size provides the best chance of detecting the rarer adverse events and, perhaps, of estimating their approximate incidence. However, incidence data are difficult to evaluate without a natural comparator group; so a section on the examination of safety from the controlled studies alone is particularly useful. The results from the controlled studies should be combined separately for placebo and active controlled studies.

The components of an ISS should include the extent of exposure, characteristics of the population, deaths, dropout analyses for serious or potentially serious adverse events, rates of common adverse events, as well as clinical laboratory results. All indications of potential toxicity arising from statistical exploration of the data should be reported. The evaluation of the reality of these potential

adverse effects should take into account the issue of multiplicity arising from the numerous statistical comparisons made. The evaluations should make use of survival analysis methods to exploit the potential relationship of adverse events incidence to duration of exposure and follow-up. The risk associated with identified adverse events should be appropriately quantified to allow a proper assessment of the risk/benefit relationships.

There are at least three reasons to pool data across studies for the safety summary. One goal is to improve the precision of the incidence estimates. This is especially important for rare events. A second goal is to improve the statistical power for detecting any risk factors that may be associated with the use of the drug and the adverse effect. A final goal is to generate hypotheses about risk that may be explored in future studies.^[8]

It is appropriate to consider carefully the pooling strategy. It is more appropriate to pool studies of a similar design. One needs to consider the patient population, dosing regimens, duration of exposure, and study methods prior to pooling. Furthermore, pooling may not give a meaningful incidence rate if the incidence rates in the individual studies differ dramatically. The differences may be important predictors of the event and should not be ignored. An example of this may be a drug for which phototoxicity was observed. Outpatient studies may reflect the adverse event, while inpatient studies would not. Therefore they should not be combined. If the incidence rates are comparable, then pooling to get a more precise estimate is appropriate.^[8]

Once the pooling has been decided and appropriate patient samples have been obtained for estimating incidence, it is important to consider important predictive factors, such as dose, plasma level, duration of treatment, concomitant medications, age, sex, and concurrent illness, among others.^[8] These factors should be looked at in combination, as well. For example, elderly patients with severe disease may be more prone to a particular side effect, especially when treated simultaneously with a particular concomitant medication. These three-way interactions are difficult to detect and require large sample sizes, and it is exactly the type of information that the clinician is interested in.

CONCLUSION

During the design of a clinical program, careful attention should be paid to the uniform definition and collection of measurements that will facilitate a subsequent interpretation of the series of trials, particularly if the data are likely to be combined across trials. A common

dictionary for recording medication details, medical history, and adverse events should be selected. A common definition of primary and secondary variables is nearly always worthwhile for replication of results. The manner in which key variables are collected, the timing of assessments, the handling of protocol violations, and the definition of prognostic factors should all be kept compatible. To change these items from trial to trial makes it difficult to summarize them into a consistent story. Changes should be made only when there is a compelling reason to do so.^[2]

Integrated summaries are the ultimate conclusion for the benefit/risk ratio of the drug therapy in humans. These are the endproduct for a typically long period during which clinical studies are performed. Therefore it is important to plan the summaries early in the clinical development program. In this way, each clinical study can be planned so that it will fit clearly into the ISE and/or the ISS and will thus be easier to design. If we "begin with the end in mind,"^[9] the plan for the integrated summaries should be written in advance and should evolve as new results are obtained.

Intention-to-Treat Analyses (ITT)

Ronald K. Knickerbocker

Pfizer Global Research and Development, Ann Arbor, Michigan, U.S.A.

Abstract

Intention to treat (ITT) is a principle used for primary analyses in most randomized clinical trials testing new therapeutic agents. This entry breaks down the statistical and scientific issues concerning an intention-to-treat analyses.

INTRODUCTION

Randomization of therapy ensures that a therapy assignment is based on chance alone. This means that the baseline characteristics (measured and unmeasured) of the therapy groups should be comparable, with any differences due to chance. Thus, differences in trial outcomes among the groups should be due only to therapy assignment. Most statistical tests of significance require randomization as a fundamental principle. Therefore, randomization is the foundation for statistical inference of prospective clinical trials comparing therapy regimens.^[1]

Intention to treat (ITT) is a principle used for primary analyses in most randomized clinical trials testing new therapeutic agents. In a randomized clinical trial, subjects are randomly assigned to different therapies or regimens. The ITT principle requires that any comparison among therapy groups in a randomized clinical trial is based on results for all subjects in the therapy groups to which they were randomly assigned.^[2] This principle helps maintain the benefits of randomization. An alternative is to analyze only a subset of the subjects, such as those deemed to be compliant. However, the subset of compliant subjects may be different from the entire randomized population in ways that can lead to incorrect conclusions. The Coronary Drug Project provides an example of the possible bias introduced when looking only at the compliant.^[3]

If the randomized subjects in a clinical trial follow the therapy regimen assigned and complete the procedures specified in the protocol exactly, then the ITT analysis is the natural analysis for looking at all data from all randomized subjects. Unfortunately, in most randomized clinical trials, a combination of predictable and unpredictable circumstances leads to a subset of subjects who are unable to follow the intended protocol exactly. These circumstances include subjects entering the trial when ineligible, subjects who do not follow their assigned therapy regimen, subjects erroneously given or assigned the incorrect

therapy, subjects who refuse trial procedures, subjects taking disallowed concomitant medication, and subjects who terminate trial participation prior to completion of the trial. These factors (along with others) lead to subsets of randomized subjects at the end of the trial who may no longer be comparable or representative of the population under study.

REGULATORY REQUIREMENTS AND GUIDELINES

The International Conference on Harmonization (ICH) Guidelines on Statistical Principles for Clinical Trials^[4] contain extensive comments on ITT principles in Section 5.2, including the following discussion:

The intention-to-treat principle implies that the primary analysis should include all randomized subjects. Compliance with this principle would necessitate complete follow-up of all randomized subjects for study outcomes. In practice this ideal may be difficult to achieve, for reasons to be described. In this document the term “full analysis set” is used to describe the analysis set which is as complete as possible and as close as possible to the intention-to-treat ideal of including all randomized subjects. Preservation of the initial randomization in analysis is important in preventing bias and in providing a secure foundation for statistical tests. In many clinical trials the use of the full analysis set provides a conservative strategy. Under many circumstances, it may also provide estimates of treatment effects which are more likely to mirror those observed in subsequent practice.

There are a limited number of circumstances that might lead to excluding randomized subjects from the full analysis set, including the failure to satisfy major entry criteria (eligibility violations), the failure to take at least one dose of trial medication and the lack of any data postrandomization. Such exclusions should always be justified. Subjects who fail to satisfy an entry

criterion may be excluded from the analysis without the possibility of introducing bias only under the following circumstances:

1. The entry criterion was measured prior to randomization.
2. The detection of the relevant eligibility violations can be made completely objectively.
3. All subjects receive equal scrutiny for eligibility violations. (This may be difficult to ensure in an open-label study, or even in a double-blind study if the data are unblinded prior to this scrutiny, emphasizing the importance of the blind review.)
4. All detected violations of the particular entry criterion are excluded.

In some situations, it may be reasonable to eliminate from the set of all randomized subjects any subject who took no trial medication. The intention-to-treat principle would be preserved despite the exclusion of these patients provided, e.g., that the decision of whether or not to begin treatment could not be influenced by knowledge of the assigned treatment. In other situations, it may be necessary to eliminate from the set of all randomized subjects any subject without data postrandomization. No analysis is complete unless the potential biases arising from these specific exclusions, or any others, are addressed.

When the full analysis set of subjects is used, violations of the protocol that occur after randomization may have an impact on the data and conclusions, particularly if their occurrence is related to treatment assignment. In most respects, it is appropriate to include the data from such subjects in the analysis, consistent with the intention-to-treat principle. Special problems arise in connection with subjects withdrawn from treatment after receiving one or more doses who provide no data after this point, and subjects otherwise lost to follow-up, because failure to include these subjects in the full analysis set may seriously undermine the approach. Measurements of primary variables made at the time of the loss to follow-up of a subject for any reason, or subsequently collected in accordance with the intended schedule of assessments in the protocol, are valuable in this context; subsequent collection is especially important in studies where the primary variable is mortality or serious morbidity. The intention to collect data in this way should be described in the protocol. Imputation techniques, ranging from the carrying forward of the last observation to the use of complex mathematical models, may also be used in an attempt to compensate for missing data. Other methods employed to ensure the availability of measurements of primary variables for every subject in the full analysis set may require some assumptions about this subject's outcomes or a simpler choice of outcome (e.g., success/failure). The use of any of these strategies should be described and justified in the statistical section of the protocol, and the assumptions underlying any mathematical models employed should be clearly explained. It is also important to demonstrate the robustness of the corresponding results

of analysis especially when the strategy in question could itself lead to biased estimates of treatment effects.

Because of the unpredictability of some problems, it may sometimes be preferable to defer detailed consideration of the manner of dealing with irregularities until the blind review of the data at the end of the trial, and, if so, this should be stated in the protocol.

The Center for Drug Evaluation and Research (CDER) of the Food and Drug Administration (FDA) has released a Guidance for the Format and Content of the Clinical and Statistical Sections of an Application^[5] that discusses ITT analyses. The subsection on data sets analyzed (in the "Efficacy Results" section) contains the following:

Exactly which patients are included in the effectiveness analysis should be precisely defined, e.g., all patients with any effectiveness observation or with a certain minimum number of observations, only patients completing the trial, all patients with an observation during a particular time window, only patients with a specified degree of compliance, etc. It should be clear, if not defined in the study protocol, when, *relative* to study completion, and how, inclusion/exclusion criteria were developed. As a general rule, even if the applicant's preferred analysis is based on a reduced subset of the patients with data, there should be an additional "intent-to-treat" analysis using all randomized patients.

The subsection on demographic and baseline features of individual patients and comparability of treatment groups contains the following statement:

If the data sets in the "intent-to-treat" analysis and the applicant's preferred analysis are substantially different, comparability of treatment groups should be examined and any other reasons for such differences should be discussed.

In the section on statistical/analytical issues, the subsection on handling of dropouts or missing data states:

The results of a clinical trial should be assessed not only for the subset of patients who completed the study, but also for the entire patient population randomized (the intent-to-treat analysis). Several factors need to be considered and compared for the treatment groups in analyzing the effects of dropouts: the reasons for the dropouts, the time to dropout, and the proportion of dropouts among treatment groups at various time points.

Procedures for dealing with missing data, e.g., use of imputed data, should be described. Detailed explanation should be provided as to how such imputations were done and what underlying assumptions were made.

The FDA also provides guidance for some therapeutic areas that refer to preferences regarding ITT analyses. For example, the draft guidelines for preclinical and clinical evaluation of agents used in the prevention or treatment of postmenopausal osteoporosis^[6] states that "Plans for imputing missing data (both fracture follow-up assessment

and BMD data) should be explained in the protocol, and one or more supplementary intent-to-treat analyses using imputed data should be performed.” Such guidelines are an important resource for studies that might support the registration of a therapy being studied.

STATISTICAL ISSUES

When designing a study, sample size calculations should consider all aspects of the primary analyses. When ITT principles are used, calculation of sample size should include assumptions about the effect of factors such as noncompliance and crossover to other active therapies that are available. These factors will generally attenuate the assumed therapy effect and lead to the need for more subjects.^[7]

SCIENTIFIC ISSUES

It should be the goal of any randomized clinical trial to develop a protocol that can be reasonably followed by at least a large proportion of the subjects in all therapy groups.^[8] However, it is fairly common to see a degree of partial or complete noncompliance with the assigned therapy regimen (it is important to note that compliance may involve more than simply taking the medication, but also following specific instructions related to use [e.g., timing of multiple doses, relationship to food intake, or the need to remain upright]). In particular, subjects may not be able to tolerate side effects perceived to be related to therapy, and may stop taking medication or switch to other therapies. Subjects may also become noncompliant because of a perceived lack of efficacy of the therapy. It is also possible for a subject to be given a different therapy than that assigned, due to error; thus, subjects may take their study medication but still be noncompliant with the *assigned* therapy. In extreme cases, noncompliance may make study inference impossible.

In cases where subjects do not follow the protocol, a natural question is whether such subjects should be excluded from analysis because they do not seem to provide information relevant to the therapy regimens being studied. The ITT principle does not allow comparisons that exclude randomized subjects, regardless of their compliance with the therapy regimens and procedures of the trial, although practically such exclusions may be necessary in cases such as subjects missing all postbaseline measurements. This ensures that the randomization is protected (i.e., all groups have comparable baseline characteristics and that any differences besides therapy are because of chance), and precludes the possibility of bias as a result of selectively excluding subjects from therapy groups, which may lead to systematic differences among the groups that are attributed to factors other than therapy assignment.

In studies with an inactive control (e.g., placebo) or where the therapy under study is more effective than the control, the ITT analysis will usually lead to attenuated estimates of the true therapy, particularly when noncompliance is limited to subjects taking nothing or other therapies under study instead of the assigned therapy. In particular, ITT analyses will generally underestimate the effects of an efficacious therapy regimen. The ITT analysis will also generally underestimate any effects of a therapy on side effects. When active alternatives are available and are used by trial participants, effects on estimates of efficacy or side effect profile are generally not predictable and depend on factors such as the effectiveness of the alternative therapy and the characteristics of the noncompliant trial participants. It should also be noted that ITT analyses can increase variability, which might mask differences in equivalence trials.^[9]

It is intuitive to want to compare therapy groups based on the subjects who complete and are fully compliant with the protocol (completers or evaluable analysis).^[10] If subjects are removed from analysis in a completely random fashion, excluding them should have no effect on estimates of response or therapy effect. However, excluding nonrandomly selected subsets of subjects from an analysis may introduce bias in the results, even if membership in the subset to be excluded is equally distributed among the therapy groups, because the subset may have different characteristics than the randomized population. For example, it has been demonstrated that subjects compliant with study medication may respond better than noncompliant subjects in both treated and placebo groups.^[3] In the case where the subjects removed from analysis are not representative of the randomized populations, but are similar among therapy arms, estimates of therapy effects will usually be unbiased, but inference will no longer be generalizable to the intended study population.

Once therapy groups are compared based on subsets of subjects not solely defined by the randomization, it is impossible to show that the subset of subjects from which the inferences are being drawn are comparable. This leads to the potential introduction of bias and limits the generalizability of the trial.^[11] An exception to this rule is removing subjects found to be ineligible based on objective data that was known or could be determined in the same manner for all subjects prior to randomization.^[12] However, if the subject is found to be ineligible based on postrandomization data, it is possible that therapy assignment could have affected the availability of the information and, thus, that subject should be included in the ITT analysis.

Intention-to-treat analyses are often considered to be more generalizable to clinical practice. In particular, when subjects in a therapy group stop taking the drug or are not fully compliant with the regimen, the response rate of the therapy declines, as it would in clinical practice. In contrast, with most objective measures, not taking study medication should have minimal effect on placebo control groups, provided that the subjects are followed to study completion. However, this advantage of generalizability

can be lost when subjects are allowed to switch to or add on other effective therapies. In this situation, active therapy arms may still be reflective of what happens to subjects who initiate therapy in clinical practice, and should not have a large effect on the therapy arm if the other therapies are similar in efficacy to that being tested. However, the placebo group will generally have a higher observed response rate than what would be seen with a group treated with placebo alone. Therefore, effective therapies will be penalized by the additional active medication use in the placebo arm. This can lead to the need for larger studies to compensate for the attenuated therapy effect because of bias in the placebo arm. It should also be noted that such crossovers may lead to overestimates of the therapy effect when other medications available are more effective than the test therapy, particularly when more subjects in the test arm take the additional agent. Careful consideration should be given to minimizing the use of additional active agents in placebo-controlled clinical trials when alternative therapies (or the therapy being studied) are available.

Finally, it should be noted that some subjects end up with missing data even when efforts are made to follow all randomized subjects. For example, subjects may terminate participation in the study prior to completion, miss or refuse procedures, or move away from the clinical center. When no postbaseline information is collected for a randomized subject, the subject may be excluded or some value indicating "failure" may be imputed. In most cases, only some of the data are missing for a subject. Even in a strict ITT analysis, data will need to be imputed for these subjects. Many methods exist for imputing missing data. Common methods include carrying forward the last value for subjects leaving the study and treating those subjects as failures.^[13] Other authors have proposed methods for imputing endpoints based on earlier data obtained in the study.^[14]^[15] The primary method for imputation should be documented prior to unblinded data analysis. Several different imputation methods can be used to confirm the primary results, evaluate the sensitivity of the primary method used, and examine the robustness of the therapy effect.

CONCLUSION

Statisticians generally agree that following the ITT principle reduces bias and is appropriate for most trials. However, there are many important decisions that need to be considered during the planning phase of data analysis, including the strictness of the application of the principle; handling

of ineligible subjects who were erroneously randomized; biasing factors, such as noncompliance, concomitant medication use, and crossover to active medications; methods for imputing missing data; and the effect of the analysis on safety or other endpoints where equivalence might be expected. Karl Peace has written that a goal of clinical research in the development of new drugs is to design protocols and conduct clinical trials so that the evaluable-only and ITT analyses are the same.^[11]

Abstract

With more and more generics becoming available in the marketplace, the safety/efficacy concerns may arise as the result of interchangeably use of approved generics. However, bioequivalence assessment for regulatory approval among generics of the innovative drug product is not required. In practice, approved generics are often used interchangeably without any mechanism of safety monitoring. In this article, based on indirect comparisons, we introduce several methods to assessing bioequivalence and interchangeability between generics. The applicability of the methods and the similarity assumptions were discussed, as well as the inappropriateness of directly adopting adjusted indirect comparison to the field of generics' comparison. Besides, some extensions were given to take into consideration the important topics in clinical trials for bioequivalence assessments, e.g., multiple comparisons and simultaneously testing bioequivalence among three generics. Two real examples, the studies of malaria generics and HIV/AIDS generics prequalified by the WHO, were used to demonstrate the use of the method.

Keywords: Adjusted indirect comparison; Average bioequivalence; Fiducial probability; Geometric mean ratio; Indirect comparison.

INTRODUCTION

Average bioequivalence assessment for regulatory review and approval between a generic and a brand-name drug is well established and widely used in the pharmaceutical industry.^[1-5] Before a generic can be approved by the United States (US) Food and Drug Administration (FDA), the sponsor is required to conduct a bioequivalence study to demonstrate that the generic is bioequivalent to the brand-name drug in terms of the rate and extent of drug absorption. Under the Fundamental Bioequivalence Assumption, two drug products are considered therapeutic equivalent if they are shown to be bioequivalent in drug absorption profile. An approved generic can then be used as a substitute of the brand-name drug. In particular, the free interchangeability is generally assumed for small-molecule generics, resulting in the substitution of various generics in pharmacies. Since small-molecule drugs are generally safe and effective, these assumptions and practices usually work. However, important exceptions exist.

When several generics are bioequivalent to the same brand-name drug, it is not obvious that they are bioequivalent to each other. Anderson and Hauck^[6] demonstrated that although with two or three generics, the probability of such lack of bioequivalence is fairly low, the concern

becomes substantial with five, six, or more products on the market. As more and more generics become available in the marketplace, and the fact that approved generics may be used interchangeably, it is a concern whether (1) the quality of approved generics is consistent and (2) the interchangeability among the approved generics is safe and efficacious. For example, with respect to the pharmacokinetic (PK) mean responses, if an approved generic A falls on the bioequivalence lower end (say 80%) of the brand-name drug and another approved generic B is on the higher end (say 120%), the relative change in response of a subject who switches from A to B could lead to a drastic change (say 50%) in blood concentration that could potentially raise a safety concern. Also, strong safety concerns were repeatedly raised about the generic-to-generic substitution of, e.g., antiepileptics^[7,8] and immunosuppressant products.^[9] However, bioequivalence assessment among generics is not required by regulatory agencies such as the FDA,^[2,10] and there is often a lack of head-to-head comparative trials between all available generics of the same brand-name drug to ensure the interchangeability between them.

As the settings of the original bioequivalence trials are not identical, using the original data directly to test the bioequivalence between generics is not recommended. To deal with this difficulty, the following two approaches

may be useful: (1) calibrate the original data based on the summary statistics of the brand-name drug from both bioequivalence trials, and then analyze the calibrated data; and (2) use the results from different trials to estimate the relative bioavailabilities between generics through indirect comparison. The latter can be a practical way, since the original study data are always unavailable and only the summary data are often accessible. Following this idea, several approaches of indirect comparison in investigating the bioequivalence between generics have been employed and reviewed.^[11–16] Among them, the adjusted indirect comparison was considered by Garcia-Arieta et al.^[12] as the simplest and most suitable method for bioequivalence studies. The adjusted indirect comparison is a useful tool for assessing the bioequivalence between two generics of the same brand-name drug, and partly preserves the power of randomized controlled trials. Nonetheless, it requires the original studies be sufficiently powered (>80%) and the point estimate difference between generics not exceed the 7% difference.^[12] To get a better performance, Garcia-Arieta et al.^[12] also extended the acceptance limit from $\pm 20\%$ to $\pm 30\%$, which seems arbitrary.

For clinical practice, the bioequivalence and interchangeability between generics make sense only if the condition that both generics are bioequivalent to the corresponding brand-name drug holds. However, directly adopting the adjusted indirect comparison does not take this condition into consideration. In view of this, the restricted confidence interval of logarithmic geometric mean ratio (GMR) for two generics was proposed,^[17] under the framework of indirect comparisons with constraints. Furthermore, the fiducial probability^[18] of bioequivalence between generics can be derived. In this article, we focused on bioequivalence testing of a basket of generics and proposed a normality-based method to screen average bioequivalence pairs of generics with certain assurance. Assume that there are two generics, denoted by G_A and G_B , respectively, which have been shown to be bioequivalent to the same brand-name drug (denoted by B_R). The available data are from two bioequivalence trials, one comparing G_A and B_R and the other one comparing G_B and B_R . The same criterion used for testing the average bioequivalence of a generic and the brand-name drug is adopted to address the testing of average bioequivalence between two generics. That is, if the 90% confidence interval of the GMR between two generics falls into a prespecified interval, say (80.00%, 125.00%), we claim that the two generics are average bioequivalent. The confidence interval of GMR is constructed based on the 90% confidence intervals from the original bioequivalence studies under normality assumption.

In the next section, we briefly discussed the adjusted indirect comparison for testing bioequivalence between generics, outlined the method of fiducial probability, and provided a detailed description under the conventional two-sequence, two-period crossover design. In Section “Some Extensions,” some extensions for the fiducial

probability method including multiple comparisons were presented. Then Section “Similarity Assumptions and Determining the Bioequivalence Limits” discussed the important assumptions of similarity and the determination of the bioequivalence limits. Two examples of malaria generics and HIV/AIDS generics were provided to demonstrate the use of the method in Section “Real Example Analysis.” In Section “Summary,” some concluding remarks were given.

RESTRICTED CONFIDENCE INTERVALS OF GMR BETWEEN GENERICS

In this section, we discuss the inappropriateness of directly applying adjusted indirect comparison to testing generics’ bioequivalence, and then introduce the fiducial probability method of restricted confidence intervals of GMR between two generics, using the normality-based statistics from two independent bioequivalence trials. The applicability of this method depends on similarity assumptions, which will be discussed in Section “Similarity Assumptions and Determining the Bioequivalence Limits.” To better illustrate the method, we provided detailed solutions under 2×2 crossover design without carryover effect in the [Appendix](#).

Denote (L_A, U_A) and (L_B, U_B) as the $1 - 2\alpha$ confidence intervals of $\mu_A - \mu_R$ and $\mu_B - \mu_R$, respectively, where μ_A, μ_B , and μ_R are the true logarithmic geometric means of G_A, G_B , and B_R , respectively. (L_A, U_A) and (L_B, U_B) are obtained from two independent bioequivalence trials with normality-based statistical method. Assume that the two trials are similar so that the relative effect estimated by the trial of G_A versus B_R is generalizable to subjects in the trial of G_B versus B_R , and the relative effect estimated by the trial of G_B versus B_R is generalizable to subjects in the trial of G_A versus B_R . Denote $(\delta_L, \delta_U) = (\log(0.8), \log(1.25))$ as the bioequivalence limits. The approval of both generics requires that both (L_A, U_A) and (L_B, U_B) fall within (δ_L, δ_U) . Based on (L_A, U_A) , (L_B, U_B) , the statistical methods used for obtaining these two confidence intervals, and the similarity assumptions, we construct the restricted confidence intervals of $\mu_A - \mu_B$ by indirect comparison.

Adjusted Indirect Comparison for Generics’ Bioequivalence

The method of adjusted indirect comparison can be described as follows: in the trial of G_A versus B_R , assume that $\mu_A - \mu_R$ was estimated as $\hat{\nu}_{AR}$. Similarly, in the trial of G_B versus B_R , $\mu_B - \mu_R$ was estimated as $\hat{\nu}_{BR}$.

Under the similarity assumption, based on indirect comparison, we get a point estimator of $\mu_A - \mu_B$ as $\hat{\nu}_{AR} - \hat{\nu}_{BR}$, of which the variance was estimated by Var_{AB} . Under the normality assumption, the $1 - 2\alpha$ confidence interval of $\mu_A - \mu_B$ for adjusted indirect comparison can be expressed as

$$\hat{v}_{AR} - \hat{v}_{BR} \pm z_{\alpha} / t_{\alpha}(df) \cdot \sqrt{\widehat{Var}_{AB}}, \quad (1)$$

where $z_{\alpha} / t_{\alpha}(df)$ is the α quantile of standard normal distribution or that of the Student's t -distribution with the degree of freedom df .

From the viewpoint of Gwaza et al.,^[13] among the available methods for performing indirect comparisons, the adjusted indirect comparison is the simplest and most suitable method for bioequivalence studies, because it uses publicly available data, and partly preserves the power of randomized controlled trials. For clinical practice, the bioequivalence and interchangeability between generics make sense only if both generics are bioequivalent to the corresponding brand-name drug. Directly adopting adjusted indirect comparison may not be appropriate since this method derives the confidence interval of $\mu_A - \mu_B$, ignoring the fact that the confidence intervals for $\mu_A - \mu_R$ and $\mu_B - \mu_R$ are contained with (δ_L, δ_U) , resulting in a narrower confidence interval and overestimation of clinical meaningful bioequivalence between generics. To mitigate this limitation, constraints on the indirect comparison were imposed and the fiducial probability type of restricted confidence intervals of $\mu_A - \mu_B$ was proposed,^[17] under the framework of indirect comparisons with constraints.

Restricted Confidence Intervals of $\mu_A - \mu_B$

In this section, we present the fiducial probability type of restricted confidence intervals of $\mu_A - \mu_B$, which is based on indirect comparisons under the constraint of bioequivalence between the generics and the brand-name drug.

Without loss of generality, in the trial of G_A versus B_R , assume that $\mu_A - \mu_R$ was estimated as $\hat{v}_{AR}$, of which the variance was estimated by $\widehat{Var}(\hat{v}_{AR})$. (L_A, U_A) can be expressed as $\hat{v}_{AR} \pm t_{\alpha}(df_A) \sqrt{\widehat{Var}(\hat{v}_{AR})}$, where $t_{\alpha}(df_A)$ is the α quantile of the Student's t -distribution with the degree of freedom df_A . Note that $t_{\alpha}(df_A)$ is the α quantile of standard normal distribution when $df_A = \infty$. Similarly, in the trial of G_B versus B_R , $\mu_B - \mu_R$ was estimated as $\hat{v}_{BR}$, of which the variance was estimated by $\widehat{Var}(\hat{v}_{BR})$, and $(L_B, U_B) = \hat{v}_{BR} \pm t_{\alpha}(df_B) \sqrt{\widehat{Var}(\hat{v}_{BR})}$. Then we obtain the fiducial distribution of $\mu_l - \mu_R$ as $\hat{v}_{lR} \pm t(df_l) \sqrt{\widehat{Var}(\hat{v}_{lR})}$, where $l=A$ or B , and $t(df_l)$ is the Student's t -distribution with the degree of freedom df_l . Denote f_l as the probability density function of the fiducial distribution of $\mu_l - \mu_R$. It is reasonable to assume that f_A and f_B are statistically independent. Based on f_A and f_B , calculate the following probability:

$$pr\{\delta_L \leq \mu_l - \mu_R \leq \delta_U, l = A, B \text{ and } -\Delta \leq \mu_A - \mu_B \leq \Delta\},$$

which is denoted as q_{Δ} . When $\Delta = 2\delta_U, q_{2\delta_U}$ is equal to $pr\{\delta_L \leq \mu_l - \mu_R \leq \delta_U, l = A, B\}$, since $\{\delta_L \leq \mu_l - \mu_R \leq \delta_U,$

$l = A, B\}$ is a subset of $\{2\delta_L \leq \mu_A - \mu_B \leq 2\delta_U\}$. For any q that $0 < q \leq q_{2\delta_U}$, we can find the minimal Δ satisfying

$$pr\{\delta_L \leq \mu_l - \mu_R \leq \delta_U, l = A, B \text{ and } -\Delta \leq \mu_A - \mu_B \leq \Delta\} \geq q.$$

Denote this minimal Δ by Δ_q . Then we get a restricted confidence interval of $\mu_A - \mu_B$ as $(-\Delta_q, \Delta_q)$ with the confidence level of q . Denote (δ'_L, δ'_U) ($\delta'_L = -\delta'_U$) as the target bioequivalence limits for $\mu_A - \mu_B$. Given the confidence level of $1 - 2\beta$, if the resulting $\Delta_{1-2\beta} \leq \delta'_U$, the clinical meaningful bioequivalence between G_A and G_B can be concluded. In other words, in this case, we have

$$pr\{\delta_L \leq \mu_l - \mu_R \leq \delta_U, l = A, B \text{ and } \delta'_L \leq \mu_A - \mu_B \leq \delta'_U\} \geq 1 - 2\beta.$$

Conversely, we can simply calculate the fiducial probability $pr\{\delta_L \leq \mu_l - \mu_R \leq \delta_U, l = A, B \text{ and } \delta'_L \leq \mu_A - \mu_B \leq \delta'_U\}$ (denoted as $q_{\delta'_U}$) and then compare $q_{\delta'_U}$ with the prespecified confidence level. If $q_{\delta'_U}$ is greater than the prespecified confidence level, we conclude that the clinical meaningful bioequivalence between G_A and G_B holds.

The fiducial probability can be expressed as

$$\int_{\delta_L}^{\delta_U} \int_{\delta_L \vee (x + \delta'_L)}^{\delta_U \wedge (x + \delta'_U)} f_A(x) f_B(y) dy dx, \quad (2)$$

and numerical integration can be used to get an accurate estimation.

SOME EXTENSIONS

In this section, we give some extensions of the fiducial probability method: getting p value to accommodate multiple comparison, a natural extension to the comparison of three generics.

Multiple Comparisons

We may encounter the issue of multiple comparisons (or multiple testing) when conducting the pairwise comparisons. In multiple comparisons, usually we adjust the significance level in some way, so that the probability of observing at least one significant result due to chance remains below the desired significance level. Specifically in practical applications, the family-wise error rate (FWER) and false discovery rate (FDR)^[19] are often considered and controlled with appropriate methods.

FWER ensures that the probability of committing a single false rejection is bounded by α . It focuses on a "family" of statistical tests and is appropriate when a single false positive in this family is a problem. The Bonferroni correction is the most common way to achieve this, which sets the significance cut-off at α / m (here m is the number of comparisons). The Bonferroni correction tends to be too

conservative, leading to a high rate of false negative or lower power, especially when the tests are correlated or m is large.

FDR is defined as the proportion of actual false positive among all discoveries (significant results).^[20] The Benjamini–Hochberg procedure^[19] is a powerful technique for controlling the FDR. It works by estimating some rejection region so that on average, $FDR < \alpha$, where α is a prespecified target value of FDR. This procedure can be briefly described as follows: put all p -values in order, from smallest to largest; the smallest one has a rank of $i = 1$, then the next smallest has $i = 2, 3, \dots$; compare each individual p -value to its own critical value, $(i\alpha)/m$, where m is the total number of tests; denote the largest p -value that satisfies $p < (i\alpha)/m$ by P_{max} ; all p -values no larger than P_{max} are significant. Although independence of test statistics was assumed in the work of Benjamini and Hochberg,^[19] addressing positive dependence by Benjamini and Yekutieli^[21] essentially assured users that this simple procedure was safe to use in many situations arising in practice, and the modification to general dependence is often not needed.^[20] Therefore, the Benjamini–Hochberg procedure is still expected to perform well in this article's case which is under the pairwise comparison setting, a specific situation of dependence. The prespecified value of the FDR should be chosen cautiously. In bioequivalence studies for generics, missing out some pairs that are actually bioequivalent will not lead to serious consequences. On the other hand, the cost of getting a false positive (leading to safety/efficacy issues) can be huge. Thus, in the case of this article, controlling a low FDR (say, 0.1) is recommended. Another approach proposed by Storey,^[22,23] the positive FDR (pFDR), deals with FDR from a different philosophy and in an opposite way. It works by first fixing the significance region, and then estimating the corresponding FDR α .

In the context of this article, we recommend using the Benjamini–Hochberg procedure for controlling the FDR. The target value of the FDR should be small. Sometimes, a “Benjamini–Hochberg adjusted p -value” is used. The adjusted p -value for a test is either the raw p -value times m/i or the adjusted p -value for the next higher raw p -value, whichever is smaller. If the adjusted p -value is smaller than the target FDR, the test is significant. In the real examples of the next section, this Benjamini–Hochberg adjusted p -value was used for controlling the FDR.

No matter which method is adopted, p -value in each single test is required for multiple testings. From Section “Restricted Confidence Intervals of $\mu_A - \mu_B$,” the p -value for the method of fiducial probability can be expressed as

$$1 - q_{\delta'_U} = 1 - pr\{\delta_L \leq \mu_l - \mu_R \leq \delta_U, l = A, B \\ \text{and } \delta'_L \leq \mu_A - \mu_B \leq \delta'_U\}$$

Simultaneous Comparison of Three Generics

We also considered the extension to accommodate the comparison of more than two generics simultaneously. In practice, other than pairwise comparison, the comparison of a basket of generics as a whole may arise. Here we consider testing average bioequivalence of three generics as a whole in terms of geometric mean. Denote G_A , G_B , and G_C as the three generics corresponding to the same brand-name drug B_R , with their logarithmic geometric means denoted by μ_A, μ_B, μ_C , and μ_R . Denote (L_A, U_A) , (L_B, U_B) , and (L_C, U_C) as three confidence intervals of logarithmic geometric means from three bioequivalence trials of G_A versus B_R , G_B versus B_R , and G_C versus B_R , respectively.

Denote f_l as the probability density function of the fiducial distribution of $\mu_l - \mu_R$. The fiducial probability $P\{\mu_l - \mu_R \in (\delta'_L, \delta'_U), l = A, B, C \text{ and } \mu_A - \mu_B, \mu_A - \mu_C, \mu_B - \mu_C \in (\delta'_L, \delta'_U)\}$ (denoted as $q_{\delta'_U}$) can be expressed as

$$\int_{\delta'_L}^{\delta'_U} \int_{\delta'_L \vee (x + \delta'_L)}^{\delta'_U \wedge (x + \delta'_U)} \int_{\delta'_L \vee (x + \delta'_L) \vee (y + \delta'_L)}^{\delta'_U \wedge (x + \delta'_U) \wedge (y + \delta'_U)} f_A(x) f_B(y) f_C(z) dz dy dx.$$

SIMILARITY ASSUMPTIONS AND DETERMINING THE BIOEQUIVALENCE LIMITS

Similarity Assumption

The methods for indirect comparison should be applied cautiously. Both clinical similarity and methodological similarity should be considered when using the methods of restricted confidence interval based on indirect comparison.^[11] First, the important conditions of the trials that could bias the estimated effect should be comparable. Patients should be similar enough in the bioequivalence trials under comparison, such that the relative effect estimated by the trial of G_A versus B_R is generalizable to patients in the trial of G_B versus B_R and vice versa. For PK/pharmacodynamic bioequivalence research, patient characteristics, the mode of drug administration, and parameter measurement should be alike between the trials involved. Second, methodological quality of the trials should be sufficiently similar. If the trials for comparison are similarly biased, it is easy to mathematically prove that the results of indirect comparison are unbiased.^[12] In addition, trials with different designs might not be comparable as the formulation effect might not be expected to be the same between them. However, Garcia-Arieta et al.^[12] considered results from conventional 2×2 crossover designs and replicate designs as combinable.

Compared with indirect comparison of efficiency trials, confidence in the clinical similarity and methodological quality of bioequivalence studies is often ensured since the basic designs of such studies are generally consistent.^[12,16]

For example, in bioequivalence trials, the participants' characteristics are frequently alike that healthy adult volunteers within the age of 18–55 years are commonly defined. Besides, randomization of subjects in the allocation of sequence are always guaranteed.

Determining the Bioequivalence Limits

Unlike the bioequivalence trials between generics and the brand-name drug that are well designed with sufficient power, indirect comparison between generics often has larger variability and reduced precision, leading to a low level of power where the bioequivalence limits are set to be the same as in the bioequivalence trial (say ($\log(0.80)$, $\log(1.25)$)). In order to enlarge the power, as recommended by Garcia-Arieta et al.,^[12–14] a slightly wider bioequivalence interval (say ($\log(0.70)$, $\log(1.00/0.70)$)) may be used for indirect comparison, as appropriate. However, cautions should be taken when relaxing the bioequivalence limits as the type I error may not be controlled below a prespecified level.

REAL EXAMPLE ANALYSIS

In this section, we used the method of fiducial probability with $\delta'_U = \delta_U$ to investigate the relative bioavailability of different generics. Two examples were illustrated to demonstrate the use of the fiducial probability method.

Malaria Generics

As in Gwaza et al.,^[13] we selected the data from three bioavailability/bioequivalence studies conducted independently, which are available in WHO Public Assessment Reports (WHOPARs) at <https://extranet.who.int/prequal/> (<https://extranet.who.int/prequal/sites/default/files/documents/MA052part6v1.pdf>, <https://extranet.who.int/prequal/sites/default/files/documents/MA062part6v1.pdf>, and <https://extranet.who.int/prequal/sites/default/files/documents/MA064part6v2.pdf>). The studies compared fixed dose combination (FDC) artemether/lumefantrine 20/120 mg tablets in adult healthy volunteers with the same brand-name drug submitted to the WHO Prequalification of Medicines Programme. These generic tablets were all compared with the brand-name drug, the WHO-approved artemether/lumefantrine 20/120 mg tablets (Coartem® / Riamet®) from Novartis Pharma (Basel, Switzerland), and had been prequalified by the WHO. The three studies enrolled 55, 64, and 58 adult males, respectively, and conducted single-center, open-label, randomized, two-period, two-treatment, two-sequence, crossover studies under non-fasting conditions. Two types of measures, the area under the time–concentration curve (AUC_{0-t} and AUC_{0-inf}) and the drug peak concentration (C_{max}), were

investigated for bioequivalence between generics. In the study performed by Cipla, an AUC truncated at 72 h was reported. Therefore, three potential pairs of generics were tested for bioequivalence, resulting in 18 comparisons after multiplying the six measures (3/3 for artemether/lumefantrine). We adjusted the p -value to control the target FDR using the Benjamini–Hochberg procedure.

Table 1 listed the 90% confidence intervals of PK parameters of artemether and lumefantrine from those reports. Based on these confidence intervals and the same size in each study, we calculated the fiducial probability for each pairwise comparison and the Benjamini–Hochberg adjusted p -value. The results were shown in the same table. Using the fiducial probability method with $\delta'_U = \delta_U = \log(125.00\%)$ and the target FDR of 0.1, all comparisons were significant and thus considered as bioequivalent except three pairs for C_{max} : Ajanta versus Ipca, Ipca versus Cipla of artemether, and Ajanta versus Cipla of lumefantrine. The results were consistent with those obtained by adjusted indirect comparison method with the conventional 80%–125% acceptance range in the work of Gwaza et al.^[13] Although three pairs of comparisons were not significant, two of them would be significant if the target FDR was set to be 0.2. The nonsignificant results might be partially attributed to the reduced precision of the fiducial probability method.

HIV/AIDS Generics

Combivir® (Lamivudine/Zidovudine) is an antiviral medication containing a combination of 150 mg lamivudine and 300 mg zidovudine. It belongs to reverse transcriptase inhibitors and helps keep the HIV virus from reproducing in the human body. Tablets are indicated for the treatment of HIV-1 infection in combination with at least one other antiretroviral agent. Several bioequivalence studies have been conducted to compare generic lamivudine/zidovudine 150/300 mg tablet with the brand-name drug Combivir® (Lamivudine/Zidovudine) 150/300 mg tablet. We selected three studies that were sufficiently similar to investigate the bioequivalence between generics, using the same method as in the previous example. The data were obtained from WHOPAR available at <https://extranet.who.int/prequal/> (<https://extranet.who.int/prequal/sites/default/files/documents/HA286part6v2.pdf>, <https://extranet.who.int/prequal/sites/default/files/documents/HA291part6v1.pdf>, and <https://extranet.who.int/prequal/sites/default/files/documents/HA392part6v1.pdf>). Each study was randomized, open-label, two-treatment, two-period, two-sequence, single-dose, and crossover. They were all conducted in healthy human adult subjects under fasting conditions performed between 2005 and 2007. The number of subjects that completed the study and were utilized for analysis to establish PK parameters and to assess bioequivalence were

Table 1 Results for the bioequivalence tests of PK parameters of artemether and lumefantrine in FDC generics

		The 90% confidence intervals for the ratio of PK parameters		
		Ajanta	Ipca	Cipla
Artemether	C_{max}	86.3–99.1	101.0–118.9	86.7–103.7
	AUC_{0-t}	93.3–104.7	102.4–116.6	90.1–106.9
	AUC_{0-inf}	93.5–104.6	102.8–117.0	90.1–106.9
Lumefantrine	C_{max}	80.3–95.4	87.6–99.5	89.3–108.2
	AUC_{0-t}	82.1–97.3	87.3–103.2	88.7–108.1
	AUC_{0-inf}	82.5–97.8	87.6–103.0	88.7–108.1
		The fiducial probability with $\delta'_U = \delta_U = \log(1.25)$ and the Benjamini–Hochberg adjusted p -value		
		Ajanta vs Ipca	Ajanta vs Cipla	Ipca vs Cipla
Artemether	C_{max}	0.795 (0.2048)*	0.996 (0.0238)	0.857 (0.1517)*
	AUC_{0-t}	0.989 (0.0255)	0.999 (0.0055)	0.962 (0.0623)
	AUC_{0-inf}	0.989 (0.0255)	0.999 (0.0055)	0.957 (0.0623)
Lumefantrine	C_{max}	0.955 (0.0623)	0.894 (0.1197)*	0.992 (0.0255)
	AUC_{0-t}	0.975 (0.0459)	0.943 (0.0688)	0.991 (0.0255)
	AUC_{0-inf}	0.980 (0.0405)	0.950 (0.0642)	0.992 (0.0255)

*Not significant by the type I method with the target FDR of 0.1.

62, 31, and 43, respectively. Three bioavailability characteristics C_{max} , AUC_{0-t} , and AUC_{0-inf} for bioequivalence evaluation were taken. Table 2 summarizes the results and the 90% confidence intervals from the reports. All comparisons were significant and thus were taken as bioequivalent except the pair of Strides versus Matrix for C_{max} of Zidovudine, with an adjusted p -value of 0.1344. The adjusted p

value of that pair was slightly larger than the target value of 0.1, partially due to the insufficient sample sizes of the original studies. The results indicated that those WHO pre-qualified Lamivudine/Zidovudine 150/300mg products are not only bioequivalent with the brand-name drug Combivir® in terms of AUC and C_{max} , but also bioequivalent between themselves with respect to AUC and C_{max} .

Table 2 Results for the bioequivalence tests of PK parameters of Lamivudine and Zidovudine in FDC generics

		The 90% confidence interval for the ratio of PK parameters

	AUC_{0-t}	1.000 (0.0001)	1.000 (0.0004)	0.999 (0.0012)
	AUC_{0-inf}	1.000 (0.0001)	1.000 (0.0004)	0.999 (0.0012)

*Not significant by the type I method with the target FDR of 0.1.

SUMMARY

The article discussed the issue of bioequivalence and interchangeability between generics that had been shown to be bioequivalent to the same brand-name drug, based on average bioequivalence in terms of GMR. Indirect comparison is a valuable way to address it. However, the recommended adjusted indirect comparison may be inappropriate from the aspect of clinical meaningful values for the parameters. The method of fiducial probability takes the clinical meaningful value into account. Extensive simulation studies not shown in this article demonstrated that this method has more power than the adjusted indirect comparison, and it controls the overall type I error below a prespecified level. The passing rate (power) is high when the true GMR is close to 1 and data noises are not large. The passing rate decreases when the true GMR departs away from 1 and approaches the bioequivalence limits. With a moderate GMR, e.g., 0.9, the method has a satisfactory power when the original studies were adequately powered. The method can be extended to simultaneous comparison of three generics and multiple testings. The applicability of the fiducial probability method requires the similarity assumptions, which should be cautiously examined in advance.

DISCLAIMER

This article has been reviewed by the FDA and determined not to be consistent with the Agency's views or policies. It reflects only the views and opinions of the authors.

Appendix: Under 2×2 Crossover Design without Carryover Effects

Let Y_{ijk} be the log transformation of the PK response of interest of the i th subject in the j th period and k th sequence of the trial. As suggested by the FDA, the following statistical model is useful in describing Y_{ijk} :

$$Y_{ijk} = \mu + F_l + P_j + Q_k + S_{ikl} + e_{ijk},$$

where μ is the overall mean; P_j is the fixed effect of the j th period, where $j = 1, 2$, and $\sum_{j=1}^2 P_j = 0$; Q_k is the fixed effect of the k th sequence, where $k = 1, 2$, and $\sum_{k=1}^2 Q_k = 0$; F_l is the direct fixed effect of the l th drug formulation ($FT + FR = 0$) when $j = k$ ($l = T$, the test formulation; otherwise, $l = R$, the reference (brand-name) formulation); S_{ikl} is the random effect of the i th subject in the k th sequence under drug formulation l ; and $S_{ik} = (S_{ikT}, S_{ikR})$, $i = 1, \dots, n_k$, $k = 1, 2$, are independently and identically distributed (*i.i.d*) bivariate normal random vectors with mean (0,0) and an unknown variance covariance matrix

$$\begin{pmatrix} \sigma_{BT}^2 & \rho^\sigma BT^\sigma BR \\ \rho^\sigma BT^\sigma BR & \sigma_{BR}^2 \end{pmatrix}.$$

e_{ijk} 's are the independent random errors distributed as $N(0, \sigma_{wl}^2)$, and S_{ik} 's and e_{ijk} 's are independent. Note that σ_{BT}^2 and σ_{BR}^2 are between-subject variances and σ_{WT}^2 and σ_{WR}^2 are within-subject variances, and that $\sigma_{TT}^2 = \sigma_{BT}^2 + \sigma_{WT}^2$ and $\sigma_{TR}^2 = \sigma_{BR}^2 + \sigma_{WR}^2$ are called total variances for the test and reference formulations, respectively.

The average bioequivalence index is $\nu = F_T - F_R = \mu_T - \mu_R$. Let $\bar{y}_{jk}$ be the sample average of the observations in the j th period and the k th sequence. Under the assumed statistical model, $\bar{y}_{11} - \bar{y}_{21} \sim N\left(\nu + P_1 - P_2, \frac{\tau^2}{n_1}\right)$ and $\bar{y}_{12} - \bar{y}_{22} \sim N\left(-\nu + P_1 - P_2, \frac{\tau^2}{n_2}\right)$, where $\tau^2 = \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho^\sigma BT^\sigma BR + \sigma_{WT}^2 + \sigma_{WR}^2 = \sigma_{TT}^2 + \sigma_{TR}^2 - 2\rho^\sigma BT^\sigma BR$. Consequently, we have the point estimators of ν and τ^2 as $\hat{\nu} = \frac{1}{2}(\bar{y}_{11} - \bar{y}_{21} - \bar{y}_{12} + \bar{y}_{22})$ and $\hat{\tau}^2 = \frac{(n_1 - 1)s_{D1}^2 + (n_2 - 1)s_{D2}^2}{n_1 + n_2 - 2}$, where s_{Dk}^2 is the sample variance based on the differences $\{y_{i1k} - y_{i2k}, i = 1, \dots, n_k\}$, $k = 1, 2$.

Denote $c = \frac{1}{4}\left(\frac{1}{n_1} + \frac{1}{n_2}\right)$, the point estimators satisfy: $\hat{\nu} \sim N(\nu, c\tau^2)$ and $\frac{(n_1 + n_2 - 2)\hat{\tau}^2}{\tau^2} \sim \chi^2(n_1 + n_2 - 2)$. Then, the $1 - 2\alpha$ confidence lower limit and upper limit of ν are given as $L = \hat{\nu} - Z_\alpha \sqrt{c\hat{\tau}^2}$, $U = \hat{\nu} + Z_\alpha \sqrt{c\hat{\tau}^2}$, where $Z_\alpha = t_\alpha(n_1 + n_2 - 2)$ is the α quantile of t -distribution with degree of $n_1 + n_2 - 2$.

Now assume that both bioequivalence trials of G_A versus B_R and G_B versus B_R are 2×2 crossover designs without carryover effects. The sample sizes of the two trials were n_A and n_B , respectively. (L_A, U_A) and (L_B, U_B) are the $1 - 2\alpha$ confidence intervals of $\mu_A - \mu_R$ and $\mu_B - \mu_R$, respectively. Denote the estimators of (ν, τ) by $(\hat{\nu}_A, \hat{\tau}_A)$ for G_A and $(\hat{\nu}_B, \hat{\tau}_B)$ for G_B . Thus, we have

$$\begin{aligned} \hat{\nu}_A &= \frac{(L_A + U_A)}{2}, \\ \sqrt{c_A \hat{\tau}_A^2} &= \frac{U_A - L_A}{-2 \times t_\alpha(n_A - 2)}, \\ \hat{\nu}_B &= \frac{(L_B + U_B)}{2}, \\ \sqrt{c_B \hat{\tau}_B^2} &= \frac{U_B - L_B}{-2 \times t_\alpha(n_B - 2)}. \end{aligned}$$

Denote $\sqrt{c_A \hat{\tau}_A^2}$ and $\sqrt{c_B \hat{\tau}_B^2}$ by S_A and S_B , respectively. To test the clinically meaningful average bioequivalence between G_A and G_B based on the restricted confidence interval with fiducial probability, first we obtain the fiducial distributions of $\mu_A - \mu_R$ and $\mu_B - \mu_R$. Taking $(\hat{v}_A, \hat{v}_B, S_A, S_B)$ as constants, we have $\mu_A - \mu_R \sim \hat{v}_A + t(n_A - 2)S_A$ and $\mu_B - \mu_R \sim \hat{v}_B + t(n_B - 2)S_B$, where $t(n_A - 2)$ and $t(n_B - 2)$ are the Student's t -distribution with the degrees of freedom $n_A - 2$ and $n_B - 2$, respectively. The fiducial probability $q_{\delta'_U} = \text{pr}\{\delta'_L \leq \mu_l - \mu_R \leq \delta'_U, l = A, B \text{ and } \delta'_L \leq \mu_A - \mu_B \leq \delta'_U\}$ can be expressed as

$$\begin{aligned} & \int_{\delta'_L}^{\delta'_U} \int_{\delta'_L \vee (x + \delta'_L)}^{\delta'_U \wedge (x + \delta'_U)} \frac{1}{S_A S_B} f_A\left(\frac{x - \hat{v}_A}{S_A}\right) f_B\left(\frac{y - \hat{v}_B}{S_B}\right) dy dx \\ &= \int_{\delta'_L}^{\delta'_U} \frac{1}{S_A} f_A\left(\frac{x - \hat{v}_A}{S_A}\right) \cdot \left[F_B\left(\frac{(\delta'_U \wedge (x + \delta'_U)) \vee \delta'_L - \hat{v}_B}{S_B}\right) \right. \\ & \quad \left. - F_B\left(\frac{(\delta'_L \vee (x + \delta'_L)) \wedge \delta'_U - \hat{v}_B}{S_B}\right) \right] dx, \end{aligned}$$

where f_A and f_B are the probability density functions of $t(n_A - 2)$ and $t(n_B - 2)$, respectively, and F_B is the cumulative distribution function of $t(n_B - 2)$. We can obtain $q_{\delta'_U}$ by numerical integration. If $q_{\delta'_U}$ is greater than the prespecified confidence level, we conclude that generic G_A and generic G_B are average bioequivalent in terms of geometric mean.

Interim Analysis

Paul Gallo

Novartis Pharmaceuticals Corporation, East Hanover, New Jersey, U.S.A.

Abstract

By interim analysis, we refer to any analysis, summarization, or presentation of clinical trial data which involves separate results produced according to treatment arm (which may be fully identified or coded, e.g., A/B), and which is produced prior to formal completion of the trial and database finalization. This entry details procedural issues and concerns as well as benefits of using interim analysis.

Keywords: Clinical trial; Interim analysis; Stopping rule.

INTRODUCTION

By *interim analysis*, we refer to any analysis, summarization, or presentation of clinical trial data which involves separate results produced according to treatment arm (which may be fully identified or coded, e.g., A/B), and which is produced prior to formal completion of the trial and database finalization. Interim analyses have, in recent years, become quite a commonplace feature of clinical trial protocols; in fact, it is rare to find a long-term clinical trial which does not include some schedule for interim examination of accruing data. Statistical and procedural guidelines for performing interim analyses are relatively recent and are, in fact, still evolving to some extent. For trials which utilize interim analyses, designing and executing these analyses properly can be very important for maintaining the integrity of the trial and full interpretability of its results.

MOTIVATION FOR THE USE OF INTERIM ANALYSES

Interim analyses can be performed for a variety of reasons. The primary motivation is to protect the well-being of patients in the study; this particularly applies in longer-term studies involving mortality or serious morbidity endpoints, or trials which include patients with severe disease conditions. Monitoring of accruing data can demonstrate whether or not there are safety concerns associated with the trial for which modification or termination might be called for. With respect to the primary endpoint of the trial, if a standard of proof for a difference between study treatments can be established, then it will often be unethical to continue the trial and expose patients in the inferior arm(s) to ineffective treatment regimens. Even if there is

not definitive evidence of a difference between treatments, if one treatment arm is trending worse than another (particularly, if this is a new or experimental treatment, or one with possible safety concerns), this might also ethically warrant termination of the trial.

Interests of the study sponsor can be a motivating factor for performing interim analyses: Prior to the planned conclusion of a trial, if a standard of proof for the effectiveness of a treatment can be achieved, or if it can be shown that an experimental treatment would not demonstrate benefit if the trial were to continue (“futility”), then savings of time and resources can be realized by early termination (a futility judgment may also entail an ethical component, similarly as in the previous paragraph: if a study will not achieve its objectives, it may not be appropriate to continue to treat patients within the trial framework).

Interim analyses may be used to verify that a trial is being conducted as planned and that there are not operational or compliance issues in the conduct of the trial that need to be addressed. Interim analyses might be performed to attempt to verify the statistical assumptions underlying the trial design (however, accuracy of such assumptions can in some cases be adequately assessed based upon blinded data). A role for interim analyses that has been a topic of much recent interest involves their use in *adaptive trial designs*, i.e., study designs in which changes may be implemented in some aspect of the conduct of the trial as it proceeds, based on accruing unblinded results (see, e.g., Ref. [1]). Adaptive trials generally require the use of specialized statistical methodology.

Occasionally, an interim analysis may be performed for purposes external to the trial. It may not be an objective of the analysis to modify the ongoing trial in any way; rather, it may be desired to obtain information, perhaps for the design of other trials or for other business purposes contingent on some knowledge which can be obtained from the

accruing results of the trial in progress. (It should be kept in mind that this can be controversial in a *confirmatory* trial, i.e., one which aims to provide definitive evidence of efficacy, due to the potential for introducing bias, for reasons we will discuss later).

The potential enthusiasm for the use of interim analyses is understandable. Through judicious use of interim analyses, exposure of patients to ineffective or unsafe treatments can be reduced, sponsor resources can be saved or refocused more efficiently, and the pace at which effective treatments reach the marketplace can be expedited. Such enthusiasm must be carefully guided, however. There are well-known statistical and procedural issues and concerns associated with interim analyses which require that they be implemented carefully and cautiously so that they do not impair the integrity of the trial and its ability to answer the scientific questions for which it was designed.

STATISTICAL ISSUES

The primary statistical issue associated with interim analysis involves protection of the significance level for the trial endpoint. If comparative treatment results can potentially be examined at a number of timepoints throughout the trial, then there may well be multiple opportunities to stop the trial and claim a significant difference among treatment arms. (Note: This may apply even if the stated objectives of the interim analyses did not consider the possibility of stopping and claiming an effect.) It is widely understood that if one were to perform a significance test on a primary endpoint at various stages of a trial and, furthermore, were to use a stopping rule based on conventional nominal significance levels unadjusted for the multiple looks, the overall significance level could become highly inflated. For example, envision a situation in which data could be examined at four timepoints during a trial (including the final analysis), with equal amounts of information accruing between each of these looks. If the trial would be stopped whenever the primary endpoint reached significance at a conventional 5% level (two-sided), the true overall significance level would, in fact, be nearly 13%.^[2] It follows that significance criteria must be determined so that the overall false positive rate across all examinations of the data is maintained at the desired level.

In this sense, interim analysis adjustment is basically a multiplicity issue. Under general assumptions, the correlation structure of the different test statistics is known—basically, it is determined by the “common” data among test statistics constructed at different timepoints—so that the desired overall significance level can be achieved. A variety of procedures have been described in the literature to address this issue so that practitioners have quite a broad and flexible arsenal of tools from which to choose to implement plans which best address the objectives of the interim analyses and maintain the integrity of the study as a whole.

Many of the more well-known procedures are mentioned and described briefly in a later section.

As mentioned previously, interim analyses may be performed for reasons which do not envision that any action will be taken in the current trial, e.g., to obtain information to be used in the design of other trials or other such purposes. Such analyses may not even involve data on the main trial endpoints. Analyses such as these, in which no actions relative to the current trial are envisioned, are sometimes referred to as *administrative* interim analyses. From a purely statistical standpoint, interim analyses which do not allow the possibility of stopping and making a formal claim should not require any adjustment of statistical criteria for the final analysis. Interim analyses performed solely to address whether there might be safety concerns which could warrant termination may also fall into this category. However, it should be considered that any review of comparative interim data could potentially set in motion a chain of events which could lead to further unblinding, and unplanned actions might possibly be taken. For example, results might be so compelling, perhaps unexpectedly positive, so that termination might be warranted on ethical grounds. In this sense, perhaps no interim analysis can be guaranteed to be completely administrative; it is somewhat a matter of judgment based on the particular details of a situation whether formal statistical adjustment of significance criteria should be employed for interim analyses which are considered to be administrative. (Another option, suggested in Ref. [3], is to impose a very trivial statistical adjustment for interim analyses which do not have the intent of stopping for positive efficacy; this thus maintains the operating characteristics of the study while providing an operational definition for an efficacy assessment in case one becomes necessary.)

Utilization of statistical methods for interim analyses can lead to complications which are somewhat unique to the interim analysis context. One of these involves estimation: if parameter and interval estimates at the conclusion of a trial are computed “naively”, i.e., unadjusted for the actual structure of interim examinations of the data and prespecified stopping rule, point estimates will be biased and confidence intervals will not provide the correct coverage. Methods have thus been developed to produce more appropriate versions; some of these are referred to in a later section.

PROCEDURAL ISSUES AND CONCERNS

The main procedural issue associated with interim analyses involves confidentiality of results: The integrity of the trial is best ensured if knowledge of interim results is carefully protected and, in particular, remains unknown to those involved in conducting the trial. Arguments underlying these concerns are well described in a U.S. FDA

guidance document.^[4] To briefly summarize the rationale: knowledge of how trial results are trending can potentially have unknown and subtle effects on the conduct of the remainder of the trial, which could bias the overall results and raise doubts about their interpretability. For example, such knowledge could potentially affect investigator attitudes and enthusiasm and, depending on the particular situation, might have an impact on the types of patients recruited, on specific details of the treatment regimen, on endpoint judgments, etc.

In addition, there is an issue regarding the ability of trial personnel to manage the study in an objective manner. While a trial is ongoing, trial management personnel will at times consider actions based on trial experiences or on emerging external information, perhaps of the type that validly lead to protocol amendments or changes to the statistical analysis plan. Such decisions must be made objectively, and not in an advantageous manner advised by knowledge of the interim results. In order to avoid possible biases or appearances of bias, it is thus clearly highly desirable to avoid having individuals with knowledge of interim results be party in any way to such activities and decisions. It is desirable that statisticians with responsibilities in the trial should remain blinded to interim results and individual patient treatment codes for several reasons: because they may be involved with data cleaning decisions and activities, because they are likely to be involved in decisions regarding finalization of the study analysis plan, and because they may have reason to be in contact with investigators or other personnel at the study sites who must remain blinded.

Thus, the integrity of a trial and the ability to validly interpret its results are best ensured by strictly controlling access to the results of any interim analyses which are performed. Inquisitiveness on the part of investigators, sponsor representatives, or other trial personnel is *not* a valid justification for being made aware of interim results. Further regulatory guidance on this issue is provided in Ref. [5], and in the International Conference on Harmonisation Document E9: “Statistical Principles for Clinical Trials,” which states:

The execution of an interim analysis should be a completely confidential process because unblinded data and results are potentially involved. All staff involved in the conduct of the trial should remain blind to the results of such analyses, because of the possibility that their attitudes to the trial will be modified and cause changes in the characteristics of patients to be recruited or biases in treatment comparisons. This principle may be applied to all investigator staff and to staff employed by the sponsor except for those who are directly involved in the execution of the interim analysis.

Of course, *some* individuals must be aware of interim analysis results in order to make recommendations or decisions relating to the objectives of the analysis.

Commonly, evaluation of interim analysis results is performed by a *Data Monitoring Committee (DMC)*. This is a group of individuals possessing the necessary expertise and experience (e.g., clinical, statistical, other disciplines relevant to the situation) charged with reviewing the interim results and making recommendations based upon them. Its members are ideally independent of all other trial activities other than as needed to carry out their duties on the DMC, and they are free of perceptions of conflict of interest. To the extent that statisticians and programmers must be unblinded to treatment codes in order to produce analysis results for a DMC to review, it is desirable that additional staff without other trial responsibilities be named to perform these tasks, for the reasons alluded to above.

When formal statistical boundaries or stopping rules are in place, it is important to keep in mind that these may not necessarily be strictly adhered to, but rather may be interpreted as more of a guideline.^[7] Statistical rules, of course, tend to be governed in large part by the principle of ensuring that the specified significance level for a primary endpoint is protected; however, a practical reality in clinical trials is that there is a much more complex set of objectives and available information to be taken into account when an action with ramifications as critical to a trial as its continuation or termination is being considered. Thus, a DMC will often consider the totality of information available to it which might include: results from safety variables or other endpoints, perhaps from a risk/benefit viewpoint; the ability of the trial to provide more definitive answers to important scientific questions if continued; new scientific information from external sources; etc. (A related statistical issue involves *overrunning*, which refers to obtaining additional data after a formal stopping criterion has been achieved. This can occur either due to a judgment of the type described above that it is appropriate for the stopping criterion to be overruled, or simply because the lag in obtaining data for an interim analysis causes valid data to be received after a decision has been made to stop the trial; see Ref. [8].)

Another issue which arises in trials with interim analyses involves the trade-off between the completeness/quality of interim data and the need to make timely decisions. If data used in an interim analysis does not accurately reflect the status of the trial at a fairly recent point in time, then patient welfare might be jeopardized, or other decisions related to the interim analysis objectives might be made less efficiently. Very often, it is difficult, if not impossible, to ensure that interim data be both timely and of the quality one would envision for a finalized trial database, depending on the nature of the endpoint and its assessment and on factors such as whether there is a formal endpoint adjudication process. Balancing the conflicting attributes of cleanliness of interim data vs. timeliness of review is very much a case-by-case decision for which no single recommendation will apply uniformly; this is an important

consideration to be taken into account when developing interim analysis plans and procedures.

In trials with interim analyses, the criteria for success in the final analyses are generally inextricably linked with the details of the interim analysis methodology used. It is thus important that the statistical details of an interim analysis plan be thoroughly specified in the protocol (or in an amendment, if a need arises for an unplanned interim analysis), and subsequent changes to the plan should also be documented prior to implementation. Processes for performing interim analyses, restricting access to treatment codes and comparative results, and the composition and operating procedures of the DMC are also important to specify in advance because, as described above, these factors can have important implications for the validity and interpretability of trial results. Final study reports will generally include analyses of all data obtained; that is, data received subsequent to a decision to terminate a trial should be included in analyses in the trial report.

Because of the potential for interim analyses to introduce bias as we have described, there may be added motivation to examine final trial data to see if there is evidence of inconsistency before and after interim analyses. A recent CHMP guidance document^[9] describes how, in any trial with interim analyses, apparent differences before and after interim analyses in the characteristics of patients enrolled or the results obtained may raise concerns about the interpretation of the overall results because of the possibility that operational bias has been introduced. These concerns may be particularly acute in adaptive trials, where the nature of the changes implemented may raise further questions about the interpretability of aggregate results. The same guidance document suggests that “simple rejection of a global null hypothesis across all stages of the trial may not be sufficient to establish a convincing treatment effect” and that methods should be pre-specified to address whether stages can be justifiably combined.

Useful discussions of some logistic, procedural, and regulatory issues associated with interim analyses can be found in Refs. [10–12]; for more comprehensive descriptions of DMC roles, responsibilities, and operational processes, see Refs. [13–15]; for discussions of these issues specific to adaptive trials, see Refs. [16,17].

DEVELOPMENT OF INTERIM ANALYSIS STATISTICAL METHODOLOGY

As mentioned above, quite a rich literature has been produced during the past few decades addressing statistical and procedural aspects of performing interim analyses in clinical trials, and much methodology has been developed. Descriptions of the development and evolution of the current methodology can be found in Refs. [18,19]; a brief but by no means complete summary is presented here.

Early ad hoc procedures describing interim analysis critical values or stopping rules were proposed by Haybittle^[20] and Peto et al.^[21] For a pairwise treatment comparison, a typical version of this type of approach proposed that a standardized normal deviate critical value of $z = 3.0$ could be used as a stopping rule at any interim analysis, without adjustment of the final analysis criteria. This illustrated the fact that for such conservative boundaries, any significance level inflation was likely to be trivial; however, such approaches obviously were quite limited with regard to implementation of efficient procedures with desired operating characteristics.

Research and interest in this topic took off with the introduction of the discrete group sequential boundaries proposed by Pocock^[22] and O’Brien and Fleming^[23] based upon the idea of repeated significance tests due to Armitage et al.^[2] For interim analyses equally spaced in terms of the amount of data accrued, Pocock boundaries on a standard normal test statistic scale corresponded to an identical z score for each interim analysis. On this same z scale, O’Brien-Fleming boundary values were governed by an inverse square-root relationship, were more conservative at early looks, and decreased to a final analysis critical value only slightly above that nominally corresponding to the desired overall significance level. As a simple illustration, for a four-look scheme with a one-sided 0.025 level, Pocock boundary values would be $z = 2.36$ at each stage, whereas the O’Brien-Fleming boundary values, in order, would be $z = 4.05, 2.86, 2.34$, and 2.02 (the corresponding single-testing criterion is of course the familiar $z = 1.96$). Under alternative hypotheses, Pocock boundaries could have a smaller expected sample size; O’Brien-Fleming boundaries paid a minimal “interim analysis penalty” and tended to yield a maximum sample size only slightly larger than the single-analysis design with equivalent level and power (the use of O’Brien-Fleming-like boundaries has been, and remains, quite popular in practice).

These early interim analysis boundary proposals were described in situations in which the analyses were equally spaced in terms of the amount of information available between them so that the number and timing of the analyses needed to be known in advance. This obviously was a constraint that was quite restrictive, given some of the practical realities of clinical trials such as the need to schedule analyses at specified calendar times, the variable nature of data accrual, etc. Lan and DeMets^[24] proposed the use of an α -spending function, or *use function*, to address these difficulties. In this approach, one only needed to prespecify the overall significance level and a monotone function which described the rate at which it was “used up.” At any particular interim analysis timepoint, the boundary would be determined according to the past and current schedule of analyses and not by future information. Among the spending functions described by Lan and DeMets were versions which approximately generalized the boundaries originally proposed by Pocock and O’Brien-Fleming.

Subsequent research resulted in extensions of these approaches into areas such as the following: accommodation of different data structures, most notably time-to-event data;^[25,26] the incorporation of lower stopping boundaries, corresponding to failure to reject the null hypothesis;^[27,28] and extension to general classes of spending functions, some of which explicitly incorporated power considerations.^[29–31]

A different methodological approach was developed by Whitehead and colleagues.^[32,33] In this approach, letting θ denote a measure of the true difference between two treatments, the boundaries are determined by the relationship between two statistics: Z , a measure of the observed difference (Note: This is not a standard normal deviate); and V , a measure of the amount of information about θ contained in the data, which will be approximately proportional to the sample size. Mathematically, Z is the efficient score for θ , and V is Fisher's information. Straight-line boundaries based upon these two statistics have been described and investigated as well as triangular boundaries corresponding to upper and lower stopping limits. This approach is fully flexible in terms of the number and timing of the analyses, allows study designs to have desired operating characteristics, and can be used to provide valid and unbiased inferences.

Another approach which has been used to assist in interim analysis continuation decisions is *stochastic curtailment*.^[34] According to this approach, conditional probabilities of outcomes at the scheduled end of the trial are calculated based upon the observed interim data, and decisions are made based upon these (typically, this conditioning assumes the prespecified null and alternative hypotheses, although the approach is not restricted to these). For example, a futility judgment might be made and a trial may be stopped, if the conditional chance of ultimate success, given the alternative hypothesis, is very low. In what might be considered an extension of this concept, the use of *predictive probabilities* has also been proposed.^[35,36] In these Bayesian or semi-Bayesian approaches, the trial outcome probabilities are calculated based upon current beliefs about the unknown parameters determined from the observed interim data itself (possibly combined with a priori assumptions). Still another approach—that of *repeated confidence intervals*^[37,38]—has some similarity to these in the sense that it can be used to provide information to assist in decision making, which is independent of any particular stopping boundary or monitoring schedule. Recent research considers additional levels of flexibility in trials with interim analyses, allowing trial modification through the application of adaptive design techniques. Generally, study stages are defined by the points at which interim analyses are performed to consider adaptations, and within-stage inferences or estimates are combined using pre-specified weights or combination functions; see, e.g., Refs. [39–44].

Correct parameter and interval estimation in the group sequential trial context has been addressed by a number of authors.^[45–48]

SOFTWARE

Much of the methodology associated with interim analyses is quite complex to implement computationally. A number of commercial software packages are available to facilitate the design and the utilization of interim analysis plans and to permit the construction of stopping boundaries and the production of valid analysis results for a variety of situations. These include *East* (Cytel Software, 2008)^[49] and *S + SeqTrial*, a module of the *S-Plus* package (Insightful, 2002),^[50] both of which incorporate a variety of methodological approaches; and *PEST4* (MPS Research Unit, 2000)^[51] which is based upon the straight-line and triangular boundaries approach of Whitehead and colleagues. The location of on-line FORTRAN programs that can be used to implement the α -spending function approach, and a description of their usage, can be found in Ref. [52].

CONCLUSION

There are clearly important benefits that can be achieved by judicious use of interim analyses in clinical trials. Properly planned and implemented, these can enable trials to achieve their objectives in a more ethical and efficient manner. The benefits accruing from interim analyses are, of course, not “free.” Interim analyses will generally require more intensive planning during the design phase of the trial: the specific interim analysis objectives and methods, and the processes governing the performance of the analyses and implementation of decisions, will all need to be carefully considered. A DMC will generally be required, along with additional staff to perform the analyses. Timely data collection and cleaning as the trial proceeds will take on added importance. Including interim analyses may cause trials to require more patients or have longer duration than they would have otherwise; on the other hand, there is also the potential for trials to be substantially shortened. When not planned and implemented carefully, interim analyses may impair rather than enhance trials, by raising questions about the integrity and interpretability of their results. Statistical methodology, software, and clinical and regulatory perspectives relating to interim analyses seem likely to continue the evolution evidenced in recent years.

Abstract

The International Conference on Harmonization (ICH) was organized to provide an opportunity for important initiatives to be developed by regulatory authorities, as well as to provide an opportunity for industry associations to promote international harmonization of regulatory requirements. This entry provides the guidelines to harmonize technical procedures.

Keywords: Efficacy; Guidelines; Quality; Safety.

INTRODUCTION

In drug research and development, health authorities in different countries have very similar-although different requirements for approval of the commercial use of drug products. As a result, pharmaceutical companies may repeatedly have to conduct similar studies or prepare different documents of the same pharmaceutical product for regulatory submission. Therefore there is a strong industrial and regulatory interest and a need in the international harmonization of requirements for drug research and development so that information generated in one country or area would be acceptable to other countries or areas. Consequently, the International Conference on Harmonization (ICH) of Technical Requirements for the Registration of Pharmaceuticals for Human Use was organized to provide an opportunity for important initiatives to be developed by regulatory authorities, as well as to provide an opportunity for industry associations to promote international harmonization of regulatory requirements.

ORGANIZATION

Currently, however, the ICH, is concerned only with tripartite harmonization of technical requirements for the registration of pharmaceutical products among three regions: the European Union, Japan, and the United States. Basically, the organization of the ICH consists of two representatives (one from a health authority and one from the pharmaceutical industry) from each of these three regions. As a result, the ICH organization consists of six parties: the European Commission of the European Union; the European Federation of Pharmaceutical Industries and Associations (EFPIA); the Japanese Ministry

of Health, Labor, and Welfare (MHLW); the Japanese Pharmaceutical Manufacturers Association (JPMA); the U.S. Food and Drug Administration (FDA); and the Pharmaceutical Research and Manufacturers of America (PhRMA). The ICH steering committee was established in April 1990: (i) to determine policies and procedures; (ii) to select topics; (iii) to monitor progress; and (iv) to oversee the preparation of biannual conferences. Each of the six parties has two seats on the ICH steering committee. The ICH steering committee also includes observers from the World Health Organization, the Canadian Health Protection Branch, and the European Free Trade Area, which have one seat each on the committee. In addition, two seats of the ICH steering committee are given to the International Federation of Pharmaceutical Manufacturers Association (IFPMA), which represents a research-based pharmaceutical industry from 56 countries outside the regions covered by the ICH. Note that the IFPMA has responsibilities to run the ICH Secretariat at Geneva, Switzerland, and to coordinate the preparation of documentation.

GUIDELINES

In order to harmonize technical procedures, the ICH has issued a number of guidelines and draft guidelines. After the ICH steering committee selected the topics, the ICH guidelines were initiated by a concept paper and went through a five-step review process given in [Table 1](#). [Table 2](#) provides a list of currently available ICH guidelines or draft guidelines. [Table 3](#) gives the table of contents for the ICH guideline on General Considerations for Clinical Trials. In addition, [Tables 4–6](#) give the tables of contents of the ICH guidelines for Good Clinical Practices: Consolidated

Table 1 Review Steps for the ICH Guidelines*Step 1*

1. A harmonized topic is identified.
2. An expert working group (EWG) is formed.
3. Each party has a topic leader and a deputy.
4. A rapporteur for the EWG is selected.
5. Other parties are represented on EWG as appropriate.
6. A guideline, policy statement, and “points to consider” are produced.
7. Scientific issues are agreed upon.
8. Sign-off and submission to the ICH steering committee.

Step 2

1. Review of the ICH document by the steering committee.
2. Sign-off by all six parties.
3. Formal consultation in accord with regional requirements.

Step 3

1. A regulatory rapporteur is appointed.
2. Comments are collected and reviewed across all three regions.
3. Step 2 draft is revised.
4. Sign-off by EWG regulatory members.

Step 4

1. Forwarding to steering committee.
2. Review and sign-off by three regulatory members of the ICH.
3. Recommendation for adoption to regulatory bodies.

Step 5

1. Adoption of recommendations by regulatory agencies.
2. Incorporation into domestic regulations and guidelines.

Annex 1 Glossary

Guidelines, for Structure and Content of Clinical Study Reports, and for Statistical Principles for Clinical Trials, respectively. From these tables, it can be seen that these guidelines are not only for the harmonization of design, conduct, and analysis, and for a report for a single clinical trial, but also for a consensus in protecting and maintaining the scientific integrity of the entire clinical development plan of a pharmaceutical entity.

CONCLUSION

ICH serves as a platform to facilitate harmonization of technical requirements for the registration of pharmaceutical products among regions and between health authority and industry. It is a step forward in the direction of globalization and in reduction of development cost for many needed drugs.

Item Response Theory

Wen-Hung Chen

Abstract

This article serves as an introduction to the item response theory (IRT) methodology for researchers who are interested in the development of healthcare measures to collect health status data for use in clinical practice, health-care research, and clinical trials. Although IRT is relatively new to health-care field, its use has increased rapidly because it provides a detailed analysis of the item performance that enables the selection of well-performed items to be included in the measure. The basic concept of IRT is to describe the relationship between the items and the underlying magnitude of the trait believed to be governing the responses to these items. Topics included in this article are history of the IRT, its basic assumptions, well-known IRT models, and an illustration of its application. Only the unidimensional IRT models are discussed in this article as they are more commonly used health-care measures. IRT is especially suitable when the number of items is large. However, it also requires a large sample size to yield robust findings. The growing experience and continuing research will lead to improvement and wider application of the IRT methodology in the health-care field even further.

Keywords: Clinical outcome assessment; Graded response model; Partial credit model; Patient-reported outcome; Psychometrics; Rasch model.

INTRODUCTION

This article serves as an introduction to the item response theory (IRT) methodology for researchers who are interested in the development of health-care measures. Health-care researchers develop measures to collect health status data for use in clinical practice, health-care research, and clinical trials. Hailed as the modern or advanced psychometric methodology, IRT has gained a foothold in developing health-related measures. IRT provided a detailed analysis of the item performance that enables the selection of well-performed items to ensure and enhance the measurement properties of the health-care measures to be developed.

The article starts with a background and a brief history of the IRT (Sections “Background” and “Brief History of IRT”, respectively), followed by the description of its basic assumptions and terminology including the discussion of model fit, item fit, and sample size considerations (Section “Basic Assumptions and Terminology”). Some well-known IRT models are then introduced (Section “IRT Models”). Only the unidimensional IRT models are discussed in this article as they are more commonly used in the development of health-related measures. The article concludes with the application of the IRT for the development of instruments for use in health care (Section “Application of IRT in Healthcare Assessment”).

BACKGROUND

Hailed as the modern or advanced psychometric methodology, IRT has gained a foothold in developing instruments in the field of health care. Some instruments are used in clinical practice or in health-care research as tools for gathering health status data, or for screening, diagnosing, or monitoring progress on specific diseases. Some instruments are developed to measure patients’ preference or satisfaction with medical treatments. The IRT methodology is of special interest for researchers whose goal is to develop instruments for use as study endpoints for clinical trials to evaluate treatment outcomes.

In order to demonstrate that a treatment is effective or safe, the instruments, called clinical outcome assessments (COAs), have to be reliable, valid, and sensitive to detect change.^[1] COAs measure a specific concept (i.e., what is being measured by an assessment, such as pain intensity) within a particular context of use.^[1] Specifically, COAs are used to capture key symptoms and psychological and functional impacts directly from patients themselves or indirectly from observers and clinicians regarding a disease condition or a treatment. This information is critical for the regulatory review of a new treatment. Such information can also assist health technology assessors and health-care payers in determining the value of a new treatment. To this end, COAs

are increasingly being used as the key study endpoints in clinical trials across a wide variety of therapeutic areas.

This article, intended to be illustrative and to provide general understanding, focuses on the use of the IRT methodology in the development of the COAs. However, the basic principles of applying IRT to the development instruments are the same regardless of whether the purpose of an instrument is for monitoring general health status, for screening or diagnosing a specific disease, or for evaluating COA in a clinical study. Whether it is developing a new instrument, modifying an existing instrument, or adapting an existing instrument for a new population, the psychometric analysis should start with examining the performance of individual items. The goal is to demonstrate that the items perform well psychometrically and together they assess what the instrument is intended to measure. Another goal of psychometric analysis is to develop the scoring algorithm for the instrument.

The IRT methodology provides a detailed analysis of item performance that is helpful in selecting items with desired measurement properties that are expected to constitute a valid and reliable instrument. Under IRT, the relationship between the items and the underlying latent (unobservable) trait or attribute of interest (e.g., depressive symptoms, pain, physical functioning) does not vary according to the study population. Also, an estimate of the standard error on an item characteristic is conditional and available for each trait level.^[2–4] In addition, with IRT, the items and the trait estimates of the individuals are placed on the same measurement scale, which allows the evaluation of whether the specific set of items adequately covers the range of the underlying traits of the target population.

As an illustration, Fig. 1 shows the distributions of the underlying trait (labeled as “Severity” with logit as the scale unit) of two groups of subjects (stable vs. exacerbation) in the upper panel, where higher values indicate individuals with higher levels of severity. The range of

“Severity” that the items assessed is shown in the lower panel, where higher values indicate the items that are more likely to match those with higher level of severity. The figure shows that the items cover a wide range of the scale, where the majority of the subjects are located on the scale from -3.5 to 3.5 . The figure also shows the separation of the underlying severity between the two groups of subjects as measured by the instrument.

The basic concept of IRT is to describe the relationship between the items and the underlying magnitude or severity of the trait believed to be governing the responses to these items. Specifically, nonlinear mathematical functions are used to describe the probability of observing a particular item response with a given level of the underlying trait. An IRT model is said to be unidimensional when it involves only a single underlying trait. A multidimensional IRT model assumes there is more than one underlying trait. Most applications of the IRT in health-related measures use unidimensional IRT models. It is not just because it is simpler and more practical, but oftentimes it is a reasonable assumption and the findings are interpretable and useful. As such, we will only discuss unidimensional IRT models that are commonly used in the development of instruments in this article.

BRIEF HISTORY OF IRT

The earliest conceptualization of the IRT may be traced back to Thurstone’s article “A Method of Scaling Psychological and Educational Tests”.^[6] Frederic Lord further formulated the concept with a cumulative normal distribution function to describe the relationship between the probability of a correct response to an item and a latent variable.^[7] Around the same time, the Danish mathematician Georg Rasch^[8] and the Austrian sociologist Paul Lazarsfeld^[9] have also proposed parallel models independently. Although the

Fig. 1 Score distribution for patients and items by state (stable, acute). Severity on the x (horizontal) axis is measured on the logit scale. Negative logits indicate less severity, and more positive logits indicate more severity. The top histogram shows the frequency distribution of subjects with stable and exacerbating conditions; the bottom histogram shows the range of severity on the set of items measured. From Jones et al.^[5] © 2011 Elsevier. All rights reserved

theoretical foundation of the IRT was established in the 1950s and 1960s, it did not gain immediately recognition of its usefulness. The main reason was the lack of a proper statistical estimation procedure for the item response models. IRT emerged as a challenger to the then dominant classical test theory by the publication of the Lord and Novick's *Statistical Theory of Mental Test Scores*.^[10] Birnbaum's proposal^[11] to replace the cumulative normal distribution function with logistic function has made the computation much more manageable. The logistic function has since become the operational model for IRT analysis. Several estimation methods have been developed since.^[12–16] Various IRT models have been introduced at the same time.^[17–21] Riding along with the advance of the computer technology, the application of IRT took off into the 1980s and 1990s and has become a common practice in educational testing.

The widespread and successful uses of IRT in educational testing did not go unnoticed by researchers who were also seeking for a better way to develop measures for use in health-care practice, health-care research, and clinical studies. The increasing interest was fueled by the growing emphasis on evidence-based medicine where the effectiveness of medical treatments should be evaluated based on how patients survive, feel, and function. The outcomes movement gained momentum with the publication of Ellwood's "Shattuck Lecture—Outcomes Management. A Technology of Patient Experience"^[22] in 1988 and the creation of the "Agency for Health Care Policy and Research" in 1989. Studies of patient-focused outcomes were recommended and health-related outcome measures were in demand.^[23] Collection of patient-focused data, such as patient-reported outcomes (PROs), necessitated the development of well-defined and reliable instruments, and their development process should be psychometrically sound and efficient.

It was only natural that researchers in health care borrowed the knowledge and experiences from the educational testing.^[23,24] Publications of PRO data analysis using IRT can be found as early as in 1996.^[25] Revicki and Cella's 1997 article formally introduced the potential of IRT for use in health outcome assessment.^[26] The first decade of the 21st century saw the explosion of the IRT application in the development of generic health status instruments, as well as disease-specific outcome assessments. Today, as in the educational testing, IRT has become a major tool for analyzing the performance and psychometric properties of the items in the development of healthcare assessments.

BASIC ASSUMPTIONS AND TERMINOLOGY

Unidimensionality

The unidimensional IRT model means that only a single underlying trait is measured by the items that constitute the instrument. That is, the instrument measures a single construct—the underlying concept of interest—such as

pain, asthma symptoms, physical functioning, or emotional well-being. A person's level on this single underlying trait gives rise to the responses to the items. Normally, whether the items belong to a single construct is the first thing that is tested before fitting the item response data to an IRT model. A common approach to test unidimensionality is through exploratory factor analysis or confirmatory factor analysis. Sometimes, however, data are fitted to an IRT model first, and then the dimensionality of the item residuals is examined using principal component analysis. The items are unidimensional if there are as many principal components of the item residuals as there are items. If unidimensionality is not supported, grouping of items should be identified and broken into subscales. In this case, the IRT model should be fit to the individual subscale that is unidimensional.

Local Independence

IRT also assumes that items that constitute the instrument are locally independent. Local independence means that the responses to a pair of items are uncorrelated when the underlying trait has been controlled (or accounted) for. In other words, except random error, the underlying trait is the only factor that governs the item responses. Item pairs are locally dependent because there is at least one other factor influencing the item responses. Local dependent indices and the correlation of the item residuals are the common approaches used to detect pairs of locally dependent items.^[27]

When examining the correlation of item residuals, the findings of correlated residuals indicate that the items are either locally dependent or are multidimensional. In this situation, the item content should be reviewed to understand the underlying causes to resolve the issue. Multidimensionality occurs when two items measure different constructs between them. Local dependence is when the two items measure the same construct but another nuisance factor(s) also affect(s) how the items are answered. When unidimensionality assumption is violated, the two items should be divided into two unidimensional subscales, if both constructs are relevant. When local independence assumption is violated, one item of the item pair should be removed for the instrument.

Item Characteristic Curve and Categorical Probability Curve

As mentioned earlier, IRT is a collection of mathematical equations that are used to describe the relationship between the probability of endorsing a given item response and the underlying trait being measured. When there are only two response categories (i.e., items with dichotomous responses), this relationship can be graphically depicted as probability curve and is commonly called an item characteristic curve or a trace line. Each of the two response categories has its own characteristic curve. However, it is sufficient to show only the curve of the response category that increases in probability because the other curve is its

mirror image with decreasing probability. Figure 2 shows the item characteristic curves of two dichotomous items. It also shows the discrimination and location parameters that are described in the next section.

When an item has more than two response categories (i.e., a polytomous item), the relationship between the response categories and the underlying trait is depicted in the same way, except that the probability curves of all response categories are plotted. They are often called the categorical response curves. Figure 3 shows the categorical response curves of an item with five response categories, labeled 0–4. As shown in the figure, each response category has a certain range on the underlying trait where it is more likely to be endorsed.

Item Parameters

The shapes of the item characteristic curve and the categorical probability curve, and their locations, are determined by the parameters embedded in IRT models. Because

Fig. 2 Item characteristic curves of two dichotomous items. The two items displayed here have the same location parameter, denoted as b , but have different discrimination parameters, denoted as a . An item with a steeper slope has a higher discrimination parameter and can better differentiate subjects at different trait levels than the other item with a lower discrimination parameter

Fig. 3 Categorical probability curves of a polytomous item. The item has five response categories. Their probabilities of being endorsed are shown across the range of the underlying traits

these parameters are used to describe the items, they are also called the item parameters. IRT models differentiate themselves by how these parameters are formulated or constrained. In health-care application, two types of item parameters are most common and useful: discrimination parameter and location parameter. Discrimination parameter, also called the slope parameter, describes how well an item can differentiate individuals at different trait levels. The discrimination parameter represents the strength of the association between the item and the underlying trait; the higher the value of the discrimination parameter, the stronger the association. The stronger the association the greater the item is able to discriminate between the low and high levels of the underlying trait.

For instance, Fig. 2 shows two items with different discrimination parameters. The item with the higher discrimination parameter can differentiate individuals at different trait levels better than the item with the lower one. In the majority of IRT models, each item only has a single discrimination parameter. Among them, some models constrain the discrimination parameter to be the same for all items, such as the Rasch model^[8] and the partial credit model.^[19]

The location parameters describe the location on the underlying trait where the item responses have a specific probability. For dichotomous items, the location parameter is usually the location of where the probability is the same for either one response (i.e., 0.5). An exception is the three-parameter logistic (3PL) model where an additional guessing parameter changes the probability at the location of the location parameter. For polytomous items, the location parameters indicate either where, on the trait level, the probabilities are the same between adjacent responses (e.g., partial credit model and generalized partial credit model)^[19,20] or where the cumulative probability of a given response and any responses above it is 0.5 (e.g., graded response model).^[17] Figure 4 shows the item characteristic curves of two dichotomous items with different location parameters.

Fig. 4 Item characteristic curves of two dichotomous items with different location parameters. Location parameters indicate the level of underlying trait where the probability of endorsing the given response is 0.5

Model Fit

As with any use of mathematical models, it is important to assess the fit of the data to the model. The fit of a model can be compared using indices of the overall model fit. One straightforward procedure is to compare the observed total score distribution to the model-predicted score distribution. Their distributions could be visually compared or the difference between them could be assessed with a statistical test such as a chi-square test. Tests are also available for comparing the fit between different models.

Item Fit

Item fit indices can help identify items that may be retained, excluded, or replaced. To assess the item fit, the key element is the residual. The residual is the difference between an observed proportion and a model-predicted (expected) proportion of a given response. Item fit indices are constructed from the residuals, and the smaller the residuals, the better the item fit. A complementary way to assess the item fit in IRT models is to examine the ordinal response categories of the items. The order of response categories should monotonically increase from low to high along the underlying trait. That is, individuals with more of the underlying trait should endorse higher response categories, while those with less of the underlying trait should endorse lower categories. Items with response categories that do not follow this pattern are considered disordered and should be examined further.

Sample Size Considerations

IRT models require large samples to obtain *stable* parameter estimates. Several factors are involved in sample size estimation and no definitive answer can be given. A rule of thumb is that a larger sample size is warranted when the number of item parameters to be estimated is large. The factors that will affect the number of item parameters to be estimated include the choice of IRT model, the number of response categories, and the number of items. Sample sizes of >100 for the basic Rasch model and 250 for the graded response model are usually sufficient for estimating the item parameters. But a sample size of up to 500 for the graded response model is recommended for stable parameter estimates.

Another factor to consider is the objective of the IRT analysis. A large sample size may not be needed to obtain an initial or descriptive picture of item performance, provided that a presentative sample is obtained. If the purpose is to obtain more robust estimates of the item parameters and use them to calculate person scores, generally a large sample size is required. Ideally, respondents should be spread fairly uniformly over the range of the underlying traits. At the minimum, there should be at least some people responding to each of the categories of every item to allow the IRT model to be fully estimated.

In this section, we highlight the matters on the model fit, item fit, and sample size considerations. More detail on these topics can be found elsewhere^[28,29] and in the references cited therein.

IRT MODELS

The unidimensional and locally independent assumptions allow the likelihood function for these IRT models to take the relatively simple form of a product over items:

$$L_i(\theta | \mathbf{Z}_i) = \prod_{j=1}^J p(z_{ij} | \theta) \quad (1)$$

where $\mathbf{Z}_i = (z_{i1}, \dots, z_{iJ})'$ represents the i th person's response pattern on an instrument composed of J items. The generic likelihood function of the IRT analysis is the same regardless of the IRT model used. It differs only in the specific form of the function $p(z_{ij} | \theta)$, where a particular IRT model is assumed. The commonly used IRT models are briefly described here in terms of their mathematical formulas.

Rasch Model

The simplest IRT model is the Rasch model or one-parameter logistic (1PL) model. Although the two models differ in their parameterization, they are interchangeable as the results of one can be obtained through linear transformation of the other. The Rasch model takes the following form:

$$P(X_j = 1 | \theta_i, b_j) = \frac{e^{\theta_i - b_j}}{1 + e^{\theta_i - b_j}} = \frac{1}{1 + e^{-\theta_i + b_j}}. \quad (2)$$

Again, the letter b denotes the location parameter. The Rasch model is applicable only to dichotomous items. In addition, the Rasch model assumes that all items are equally discriminating that is reflected by a constant slope parameter of 1.

2PL Model

On the other hand, the 2PL model does not assume that all items are equally discriminating. Therefore, each item has its own discrimination parameter. This discrimination parameter is denoted by the letter a . The following equation presents the formula of the 2PL model:

$$P(X_j = 1 | \theta_i, a_j, b_j) = \frac{e^{a_j(\theta_i - b_j)}}{1 + e^{a_j(\theta_i - b_j)}} = \frac{1}{1 + e^{-a_j(\theta_i - b_j)}}. \quad (3)$$

As mentioned earlier, the discrimination parameter is also called the slope parameter, because it determines the flatness or steepness of the item characteristic curves.

The bigger the value of the a parameter, the steeper the slope, and the higher the discriminatory power of the item. Like the Rasch model, the 2PL model is also only applicable to dichotomous items.

Partial Credit Model

The most useful IRT models for use in the instrument development are perhaps the polytomous IRT models. This distinction is owing to the fact that, in a typical health-care instrument, the items are often constructed with multiple response categories on an ordinal scale such as a Likert scale, verbal rating scale, or numeric rating scale. For example, it is more informative to know whether a patient is having no, mild, moderate, or severe pain than knowing whether a patient is having or not having pain.

For items that have more than two ordered response categories, the Master's partial credit model is often used.^[19] The Master's partial credit model is the polytomous extension of the Rasch model. Under the Master's model, the probability of a response in category k for an item with m_j categories can be written as follows:

$$P(X_{ij} = k | \theta_i, b_{j1}, b_{j2}, \dots, b_{j, m_j-1}) = \frac{\sum_{v=1}^k (\theta_i - b_{jv})}{1 + \sum_{g=1}^{m_j-1} \sum_{v=1}^g (\theta_i - b_{jv})} \quad (4)$$

and

$$P(X_{ij} = 0 | \theta_i, b_{j1}, b_{j2}, \dots, b_{j, m_j-1}) = \frac{1}{1 + \sum_{g=1}^{m_j-1} \sum_{v=1}^g (\theta_i - b_{jv})}. \quad (5)$$

As Eq. 4 shows, under the partial credit model, each item has $m - 1$ number of b parameters. However, unlike the b parameter in the Rasch or 2PL model, for the partial credit model, the b parameters are not the location where the probability is 0.5. Instead, the b parameters are where the probability is the same for two adjacent responses. Thus, the b parameters in the partial credit models are called the item-step (or item-threshold step) parameters to distinguish them from the location parameters. A special case of the partial credit model, the Andrich's rating scale model^[30] also assumes that the item-threshold steps are equal across all items. These three models—Rasch model, partial credit model, and rating scale model—can be called the Rasch family of models.

Generalized Partial Credit Model

The other commonly used polytomous IRT models are the generalized partial credit model^[20] and the graded response model.^[17] The generalized partial credit model, as its name

indicated, is a general form of the partial credit model. Specifically, in the generalized partial credit model, the discrimination parameters are not constrained to be unity; instead, each item has its own discrimination parameter like the 2PL model. That is, in addition to the $m - 1$ number of location parameters, each item has one additional discrimination parameter. The generalized partial credit model takes the following form:

$$P(X_{ij} = k | \theta_i, a_j, b_{j1}, b_{j2}, \dots, b_{j, m_j-1}) = \frac{e^{\sum_{v=1}^k a_j (\theta_i - b_{jv})}}{1 + \sum_{g=1}^{m_j-1} e^{\sum_{v=1}^g a_j (\theta_i - b_{jv})}} \quad (6)$$

and

$$P(X_{ij} = 0 | \theta_i, a_j, b_{j1}, b_{j2}, \dots, b_{j, m_j-1}) = \frac{1}{1 + \sum_{g=1}^{m_j-1} e^{\sum_{v=1}^g a_j (\theta_i - b_{jv})}}. \quad (7)$$

Graded Response Model

Samejima's^[17] graded response model is perhaps the most familiar polytomous IRT model that is used in the instrument development in health care. Formulated conceptually differently, the graded response model first dichotomizes the multiple responses to responses less than k versus responses of k or higher. The probability of observing a response of k or higher is monotonically increasing as the underlying trait increases. The logistic function used to describe this probability is the same as the IRT models for dichotomous item responses (i.e., 2PL). The probability of observing a response of k is then the difference between the probability of observing a response of k or higher and the probability of observing a response of $k + 1$ or higher:

$$P(X_{ij} = k | \theta_i, a_j, b_{j1}, b_{j2}, \dots, b_{j, m_j-1}) = \frac{1}{1 + e^{-a_j (\theta_i - b_{jk})}} - \frac{1}{1 + e^{-a_j (\theta_i + b_{j(k+1)})}} \quad (8)$$

and

$$P(X_{ij} = 0 | \theta_i, a_j, b_{j1}, b_{j2}, \dots, b_{j, m_j-1}) = 1 - \frac{1}{1 + e^{-a_j (\theta_i + b_{j1})}}. \quad (9)$$

With the graded response model, for each item, the item parameters are the discrimination parameter, a , and the $m - 1$ b_{ik} parameters. These b_{ik} parameters, called the category threshold parameters, show the point on the scale of the latent trait at which the probability passes 50% for endorsing a response of k or higher. The higher the category threshold parameter, the higher the level of the underlying trait required to pass 50% probability.

Choosing an IRT Model

The characteristics of the Rasch family of models are that they assume all items have uniform discriminatory power. Under the Rasch family of models, persons are ordered the same in terms of predicted responses regardless of the location of the items. Similarly, items are ordered the same in terms of predicted responses regardless of the underlying trait of the person. From the Rasch family of models' perspective, the discrimination parameter represents a person-by-item interaction, with the item curves crossing, making the ordering of persons or items no longer invariant. Under the Rasch family of models, only the b parameters need to be estimated. The b parameter of the Rasch family of models is similar to the percent correct or average score in the classical test theory. In IRT models, in order to estimate the item parameters, one has to assume the values or distribution of the underlying trait (i.e., θ). Unique to the Rasch family of models, the raw sum scores of the persons are the sufficient statistics of the θ . That is, the θ can be estimated sufficiently with the raw sum score alone. This property makes the sample size requirement smaller for the Rasch family of models than that for other IRT models.

Perhaps the greatest advantage of the Rasch family of models from the perspective of the users is that there exists a one-to-one correspondence between the observed sum score and the IRT θ score. For example, this property would enable clinicians and patients to directly link the PRO score to the content of the instrument and, therefore, facilitate interpretation of the score. With a direct correspondence of the observed sum score to the instrument's IRT scale score, the patient's condition can be immediately assessed without waiting for the assessment result to be reported back after a complex calculation of the IRT scale score. This is a very attractive property especially when a paper form of the instrument is used. However, the advantage of speedy scoring of the Rasch family of models is diminished nowadays by the ever-present personal electronic device, such as a tablet or a smartphone, where the complex calculation can be performed in real time.

The strength of the Rasch family of models is also its limitation. Uniform discrimination of all items may not be supported for some instruments or for certain conditions. For example, while patients with lung cancer may experience three major symptoms—fatigue, chronic pain, and shortness of breath—the symptom shortness of breath may be more discriminating between mild and severe patients than the symptom fatigue. In this situation, IRT models in the form of generalized partial credit model and graded response model, which do not assume uniformity across items with respect to the discrimination parameter, may be more appropriate. The advantage of these IRT models is that they sometimes fit the data better depending on the strength of the association between the items and the underlying trait. This property allows the further evaluation of

which items are more relevant than the other items. On the other hand, having to estimate the extra discrimination parameters for each of the individual items means a larger sample size is necessary.

Another advantage of the non-Rasch family IRT models is that they are suitable for use to develop computerized adaptive testing (CAT).^[2,31] In CAT, the estimate of an individual's score can be obtained with fewer items than normally would by using a fixed-length instrument. This is achieved by selecting the next item to be administered based on the estimated score from the responses of preceding items. By selecting items that are most informative and closest to the estimated level of the underlying trait, fewer items are needed to reach the desired precision of the score. The disadvantage is that CAT requires expertise in both IRT methodology and computer system implementation. In addition, to take the advantage of a CAT, an item bank with a large number of items is also needed. If an instrument has only few items, a fixed-length form may be more economical and feasible.

Choosing an IRT model requires good understanding of the underlying construct that the instrument is intended to measure, as well as the objective of measuring that construct. The feasibility (e.g., sample size) and the intended use (e.g., generic vs. disease-specific) are also the factors to be considered. Ultimately, the decisive factor should be whether the IRT model of choice can produce interpretable results for decision-making purposes. As mentioned earlier, items with multiple category responses are often used in health-care assessments because they yield more useful information. In this case, polytomous IRT models should be used, and the choice of IRT model comes down to the partial credit model, rating scale model, generalized partial credit model, or graded response model. Choosing between the generalized partial credit model and the graded response model is less of an issue as the two models generally yield very similar results and won't affect the findings; the choice often is based on the researcher's familiarity with each of the models.

APPLICATION OF IRT IN HEALTH-CARE ASSESSMENT

The growing emphasis on the patient-focused care and treatment development has accelerated the demand and use of well-developed, reliable, and fit-for-purpose health-care assessments. These assessments take many forms; they may be oral or written, or they may require performance. These assessments may be administered electronically or on paper, and may be self-reported or administered by an interviewer. The assessments may be reported by the patients themselves, clinicians, or observers such as patients' caregivers. Regardless of the form, administration mode, or type of assessments, the measures must be valid and the results must be interpretable, especially when

critical health-care decisions are to be based on the results of these assessments.

To develop a new assessment that is well defined and reliable, one starts with the basic unit of an assessment: the items themselves. Well-planned assessment development typically begins with defining the context-of-use that includes the identification of the target population, concepts of interest, and intended use. Frequently, developing a conceptual framework and an endpoint model is the best way to define and visualize the context of use of an assessment.^[1] The next step is to determine which appropriate format, administration mode, and type of assessment are appropriate for the intended context of use. The next step in the development process is to create the items.

Once the items created are deemed measuring the intended concepts by exhibiting content validity, quantitative data should be collected in order to examine the performance of these items. First, from the item response frequency distribution, we know how the response categories are used by the individuals and how many missing item responses there are. Through examination of the IRT unidimensional assumption we know whether the items measure the same construct or multiple constructs. This information will help confirm the conceptual framework or how it should be modified.

If the Rasch family of model is used, through the item model fit statistics we will know which items do not conform to the uniform discrimination property. If non-Rasch family polytomous IRT models are used, the discrimination parameters inform about the strength of the association of the items with the underlying trait, which provide insights into how well each of the items discriminates for various levels of the underlying trait.

Next, by examining the categorical probability curves, we are able to discover whether the response categories are ordered correctly on the underlying trait. The lower response categories should occupy the lower range on the trait scale, and the higher response categories the higher range. The upper panel of Fig. 5 shows the categorical probability curves where the response categories are positioned in the correct monotonic order. In contrast, the lower panel of Fig. 5 shows the curve of response category 1 is completely overlapped with the curve of response category 0, indicating that one of these categories is ordered incorrectly.

Finally, the item-step parameters or the category threshold parameters show the range on the underlying trait that the items measure and whether there are gaps on the scale that we do not have items to measure them. This step can also be aided by plotting the test information function curve. Test information function curve helps visualize where the measurement on the underlying trait is most precise and where it is not. Altogether, through the IRT application, we obtain the information that enables us to select or remove items, or to add new items, so that the assessment covers the target range on the underlying trait with desirable precision.

Fig. 5 Categorical probability curves of two hypothetical items. The upper panel shows an item with correctly ordered response categories. The lower panel shows an item with incorrectly ordered response categories

CONCLUSION

This article serves as an introduction to the IRT methodology for researchers who are interested in the development of health-care measures. IRT provides a detailed analysis of the item performance that enables the selection of well-performed items to ensure and enhance the measurement properties of the health-care measures to be developed. IRT is especially suitable when the number of items is large. However, it also requires a large sample size to yield robust findings. Choice of an IRT model depends on the construct to be measured, the purpose of developing the tool, and the practical considerations such as the sample size. Its use in the health outcome assessment has increased rapidly. The growing experience and continuing research will lead to improvement and wider application of the IRT methodology in the health-care field. This, in turn, will lead to better tools for assessing health outcomes and health status and, ultimately, help better communication of treatment benefit and decision-making for the patients and clinicians.

IVRS/IWRS for Randomization

Mon-Gy Chen

Department of Biostatistics, Amgen, Thousand Oaks, California, U.S.A.

Abstract

The interactive voice response system (IVRS) and the interactive web response system (IWRS) have applications ranging from widely used banking services to clinical trials. This entry describes the application of IVRS/IWRS to patient randomization and drug management in clinical trials.

Keywords: Randomization; Telephony; Voice response; Web response.

INTRODUCTION

The rapid development of the Internet and web browsers as well as computer telephony technology around the turn of the twenty-first century has enabled the automatic interchange of information between a computer and a digital phone or a web-based system. It has many applications in industry. The interactive voice response system (IVRS) and the interactive web response system (IWRS), for example, have applications ranging from widely used banking services to clinical trials.

The IVRS uses a phone as an input device and responds with a computer-controlled, high-quality digitized human voice whereas the IWRS uses the Internet and a web browser. The multilingual computer response capability enables IVRS/IWRS to function worldwide 24 hours a day and to collect real-time online quality data. These features make IVRS/IWRS an ideal tool for patient randomization and drug management for both national and international clinical trials.

OVERVIEW

This entry describes the application of IVRS/IWRS to patient randomization and drug management in clinical trials. We start with a description of the traditional randomization and drug management procedure, followed with a description of the application of IVRS/IWRS to mapping patient randomization to the drug management system, and end with a description of a stand-alone patient randomization system, including a minimization procedure.

For our discussion, “randomization” is defined as a process by which each subject has an equal chance or a prespecified probability of being assigned to one of the treatments in a study. This process generates a randomization schedule containing patient numbers and the corresponding treatment assignments.

The drug management system involves several activities: packaging of clinical supplies, shipping them from a warehouse to study sites, and dispensing them to patients by a third party. Unless otherwise specified, a double-blind randomized study is assumed. The terms “drug” and “treatment” are used interchangeably.

TRADITIONAL APPROACH TO RANDOMIZATION AND DRUG MANAGEMENT

In a double-blind randomized clinical trial, much pre-study preparation needs to be completed before a site can enroll and randomize the first eligible patient. One such preparation involves the design and generation of a randomization schedule and a plan to manage and ensure an adequate drug supply throughout the study. The traditional approach, which links a patient number to the clinical supply containing the treatment for that patient, is described as follows:

1. The statistician generates the randomization schedule according to the specifications in the final protocol. The end product is a schedule containing patient identification numbers and the corresponding treatment assignments. The total number of patients generated in the randomization schedule depends on the sample size required for the study and the projected number of dropouts.
2. A copy of the validated randomization schedule is sent to the Clinical Supply Group.
3. The Clinical Supply Group prepares and packages the drug supply according to the randomization schedule. In general, an extra drug supply of at least 20% is recommended to cover any potential drug wastage during the study.
4. Individual patient kits, each of which contains the treatment assigned by the randomization process,

are prepared. Each kit is labeled with a patient number only. The treatment code is either printed on the blinded portion of a two-part label or kept in a sealed envelope and secured by a third party at the site or at a central location. In either case, the seal or the blind for a given patient can be broken only in case of a medical emergency and for that patient only.

5. A prespecified, fixed quantity of drug supply is shipped to a given site before the first patient is randomized. If a permuted-block randomization is used within a site, the drug supply sent to a site needs to be in multiples of block size. A permuted block of size 4 in a two-treatment randomization results in two repeats of the two treatments in any random order.
6. When the first patient becomes eligible at a site, the kit labeled Patient Number 1 is dispensed by the pharmacist or designee at that site. The next patient receives the kit labeled Patient Number 2. This process continues until the last patient has been randomized at the site or until study termination.
7. If the number of patients enrolled at a site exceeds the drug supply, then an additional drug supply needs to be shipped in a timely fashion before the next patient is ready for randomization. On the other hand, if a site enrolls fewer patients than the drug supply, then the remaining drugs will be wasted.

The process works as follows. Assume a study has a randomized, double-blind, parallel-group design. Two treatments, A and B, are to be evaluated in a total of 16 patients at two study sites. A permuted-block design with a block size of 4 is used. That is, for every four patients randomized, two are assigned to treatment A and two are assigned to treatment B. According to these specifications, a randomization schedule is generated (Table 1).

The Clinical Supply Group, upon receiving the randomization schedule, packages eight kits containing drug A, labeled Patient Number 1, 4, 5, 8, 9, 11, 14, or 15, and the other eight kits containing drug B, labeled Patient Number 2, 3, 6, 7, 10, 12, 13, or 16. Because each center plans to randomize eight patients, the kits labeled Patient Numbers 1 to 8 are shipped to site 1 and the kits labeled Patient

Numbers 9–16 are sent to site 2. Note that the number of patients enrolled at each site has to be in multiples of the block size to maintain treatment balance.

The first patient randomized at site 1 is dispensed the kit labeled Patient Number 1 and therefore receives treatment A. The first randomized at site 2 is dispensed the kit labeled Patient Number 9 and therefore receives treatment A. The second patient randomized at sites 1 (Patient Number 2) and 2 (Patient Number 10) receive treatment B. This process continues until the enrollment is complete or the study is terminated for other reasons.

In this example, each patient in the study has a unique patient number. Alternatively, each site can number the patient starting with 1 according to the chronological order of entry. In this case, the unique patient number for the study consists of the site number and the patient number. Applying this method, Patient Numbers 9–16 at site 2 in the example would now become Patient Numbers 201–208. The leading digit “2” identifies the site number and the second and third digits are for numbering the patients within a site. Thus the patients at site 1 will now have Patient Numbers 101–108. In this numbering system, it is important to have both the site number and the patient number preprinted on the label of the drug supply.

PROBLEMS ASSOCIATED WITH THE TRADITIONAL APPROACH

A number of problems arise with the traditional approach to randomization and drug management. One concerns the wastage of drugs as a result of the inability to share drug supplies between sites; another is the inability to ensure treatment balances across sites.

In our example, suppose that only two patients were randomized, one from each site. Only two kits would be used. Because 14 of the total 16 kits would not be used, the overall wastage for the study would be 87.5% (14/16). According to the randomization schedule, both patients enrolled would be assigned treatment A. Ideally, when a study enrolls two patients; it is preferable to have both treatments represented. In order to accommodate this type of treatment balance across sites, a central randomization is needed. Under the traditional approach, it would be impossible to balance the treatment codes across all sites. Because the rate of enrollment in clinical trials varies (some sites enroll patients rapidly whereas others may enroll a few or none at all), the traditional approach does not have a mechanism to allow for adjusting the drug supply when a site does not perform (i.e., drug wastage) or a site over enrolls (i.e., drug shortage).

These problems are readily resolved by using IVRS/IWRS. The wastage problem can be overcome by assigning patient numbers independent of the supply kits and dynamically matching them through IVRS/IWRS at the time of randomization. The IVRS/IWRS, which is accessible to

Table 1 Randomization Schedule

Patient	Treatment	Patient	Treatment
1	A	9	A
2	B	10	B
3	B	11	A
4	A	12	B
5	A	13	B
6	B	14	A
7	B	15	A
8	A	16	B

all sites at all times, is ideal for providing central randomization to check treatment balance across sites. The following section describes the use of IVRS/IWRS in drug management and patient randomization.

HOW DOES THE INTERACTIVE VOICE/WEB RESPONSE SYSTEM WORK?

The interactive voice/web response system has the capability of linking information from different tables stored in the relational database and performing queries using common identifiers. With this capability, a randomization schedule such as [Table 1](#) can be separated into many different tables and connected by IVRS/IWRS at the time of randomization. This mapping process allows IVRS/IWRS the flexibility to perform many special functions unmatched by the traditional randomization approach. The following section explains some of these features and the connection of tables by IVRS/IWRS.

DRUG SUPPLY AND PACKAGING

As already mentioned, if the drug supply can be packaged separately, independent of the patient numbers and the randomization schedule, with only the minimal quantity shipped to a site when the site is ready to randomize the first patient, the savings in the drug supply can be enormous. The Clinical Supply Group can package the drug as soon as the total supply of each drug type is known.

Let us apply this approach to our earlier example, in which 16 kits need to be packaged. The Clinical Supply Group, without the knowledge of the randomization schedule, can package the drug in two groups: eight kits for treatment A and eight kits for treatment B. The kits can be labeled with any numbering system unrelated to the patient number. The simplest method is to label the eight kits containing treatment A with consecutive numbers d01–d08 and the eight kits containing treatment B with numbers d09–d16. However, this method, although straightforward, risks revealing the treatment codes through clever guesswork.

An alternative approach is to scramble the kit numbers before treatment assignment. One such sequence for 16 kits might be d02, d05, d10, d06, d13, d09, d12, d08, d16, d011, d07, d03, d014, d04, d15, and d01. The next step is to assign the first eight numbers to kits containing treatment A and the last eight kits containing treatment B. After the assignment, the kit numbers within each treatment group can be sorted in an ascending order for easy packaging and assembling. The resulting kit numbers are displayed in [Table 2](#).

After the kit numbers have been assigned, the Clinical Supply Group can package the drugs accordingly and store them in a warehouse ready for shipment. At this

Table 2 Kit Numbers

Treatment A	Treatment B
d02	d01
d05	d03
d06	d04
d08	d07
d09	d11
d10	d14
d12	d15
d13	d16

point, the kits are not associated with any patient number or any study site. When a site is anticipating the first eligible patient, a minimal quantity containing equal numbers of treatment A and treatment B is shipped to the site. The minimal quantity of an initial shipment depends on a number of factors—it must take into account the enrollment rate at each site, and, preferably, it must be in multiples of the block size in the case of a permuted-block design. If a site can enroll four patients a day, the initial shipment has to be eight kits or more to ensure an adequate drug supply. In our example, the enrollment is assumed to be one patient per week at all sites; therefore an initial shipment of four kits, two treatment A and two treatment B, is acceptable. The first site to request shipment receives kit numbers d01, d02, d03, and d05, and the next site receives kit numbers d04, d06, d07, and d08; the contents, however, remain blinded to the site. In theory, an initial shipment of two, one for each treatment, is sufficient; however, this is not recommended in practice because of the potential risk of revealing the drug codes by the staff at the site.

As soon as the file containing kit numbers is available, as in [Table 2](#), it is loaded into the IVRS/IWRS relational database, which is accessible through a phone or website. When a site is ready for randomization, IVRS/IWRS notifies the warehouse to ship the initial supply to the site. The kit numbers and the associated site number are recorded in the IVRS/IWRS database. The system is then ready to manage (i.e., dispense or resupply) the drug supply.

When the drug supply is low, IVRS/IWRS will trigger the warehouse to resupply the site. For a slow-enrolling site, the trigger point may be one of each treatment type remaining at the site. For a fast-enrolling site, the trigger point depends on the enrollment rate. For example, if a site enrolls four patients a day, the trigger point has to be at least four kits remaining at a site, two of each drug type. The quantity of resupply also depends on the enrollment rate and how close it is to the study completion. When the study approaches its completion, no more resupply is needed. The trigger point and the quantity of resupply must be established when the IVRS system is being developed for the study.

RANDOMIZATION SCHEDULE

In the traditional approach, the randomization schedule (see [Table 1](#)) is used for packaging, shipping, and dispensing; a patient number is associated with a kit. With IVRS/IWRS, the same schedule is used, but the process is more flexible and has additional features.

One advantage of using IVRS/IWRS is its ability to separate patient numbers from the randomization codes and to match them dynamically at the time of randomization. The randomization codes serve as a bridge between the treatment assignment and any patient numbering system. This bridge is formed at the time of randomization. For example, [Table 3](#) uses the same randomization schedule as [Table 1](#), but the patient numbers are now randomization codes; these codes are not associated with patient numbers.

Assume that the patients are sequentially numbered at each site, starting with 1. When the first patient at site 1 (Patient 101) is ready for randomization, the site calls IVRS or enters the required information on the web page, which would then search through [Table 3](#) stored in the IVRS/IWRS database for the next available code and the treatment it is linked to. In this case, code 1 is available; hence Patient 101 is assigned to treatment A. If the next patient is from site 2 (Patient 201), this patient is linked to code 2 by IVRS/IWRS and treatment B is assigned. Should the study be terminated at this point, there will be two patients from the two sites, one assigned to treatment A and the other to treatment B.

Thus a central randomization is achieved. In this type of randomization, all the randomization codes are shared by all patients from all sites. The end result is a central randomization, with a balanced treatment across all sites but not necessarily within one site.

If, however, the study is designed to have treatment balance within a given center, then the IVRS/IWRS database needs to be constructed so that codes 1–8 are reserved for site 1 and codes 9–16 for site 2. With this new structure, the second patient in our example (Patient 201) would be linked to code 9, receiving treatment A, instead of code 2, receiving treatment B.

Table 3 Randomization Codes

Code	Treatment	Code	Treatment
1	A	9	A
2	B	10	B
3	B	11	A
4	A	12	B
5	A	13	B
6	B	14	A
7	B	15	A
8	A	16	B

MAPPING BY INTERACTIVE VOICE/WEB RESPONSE SYSTEM

After the clinical supply list (see [Table 2](#)) and the random assignment of treatment (see [Table 3](#)) are separated and available, they are stored in the IVRS/IWRS relational database. The IVRS/IWRS can query the database and connect these tables at the time of randomization and respond to the caller with real-time randomization and drug assignment. This mapping process is described as follows:

1. To ensure system security, an entry from any site must first pass stringent system and study-specific security measures (e.g., site identification, password, caller identification) to continue the dialog with IVRS/IWRS. For reference, a sample IVRS script is given in the [appendix](#) to this entry.
2. Through the phone keypad or the web page, any pre-specified study and patient information can be collected, which may include site and patient numbers, patient eligibility, and other patient characteristics, into the IVRS/IWRS database.
3. As soon as the eligibility is verified, IVRS/IWRS searches the randomization schedule ([Table 3](#)) for the next available randomization code and the corresponding treatment.
4. Once the treatment is identified, IVRS/IWRS then searches the drug supply list ([Table 2](#)) for the next available kit number containing the treatment at that site.
5. The IVRS, through the voice response system, informs the caller which kit number to dispense, without revealing the treatment code. In case of IWRS, the dispensing information is delivered via an e-mail or on the screen.
6. The randomization procedure is complete when the caller confirms the kit number by means of the phone or by e-mail. The entire process takes no more than two minutes.
7. The IVRS/IWRS stores the site, patient, and kit numbers as well as the treatment assignment in the database.
8. The IVRS/IWRS checks the drug supply at the site to assess the need for resupply.

Let us now illustrate by extending our earlier example. [Fig. 1](#) provides a graphic presentation of the mapping process for this example. Let us assume the study calls for a central randomization and a patient numbering system by site. The randomization schedule in [Table 3](#) and the kit list in [Table 2](#) are stored in the IVRS/IWRS database. Because of a slow enrollment rate, an initial shipment of four kits is provided to each site: kits d01, d02, d03, and d05 are sent to site 1, and d04, d06, d07, and d08 are sent to site 2. The trigger point for resupply is set at the time when two kits (one of each treatment) still remain at the site.

Fig. 1 Relational database for randomization and drug assignment

If the first entry is from site 1 (Patient Number 101), IVRS/IWRS matches this patient to the first available randomization code in Table 3, i.e., code 1, which is linked to treatment A. The IVRS/IWRS then searches Table 2 for the next available kit containing treatment A in site 1, i.e., d02. The IVRS/IWRS informs the site to dispense kit d02 without revealing its contents. The double-blind status of the study is therefore maintained. After confirmation that kit d02 has been dispensed, IVRS/IWRS checks the trigger point for resupply. Because the site still has three kits, IVRS/IWRS will not generate a resupply notice.

Applying the same approach, if the next patient comes from site 2 (Patient Number 201), IVRS/IWRS maps this patient to code 2 in Table 3 and hence assigns treatment B and kit d04. Again, no replacement kit is needed.

If the study is terminated after two patients have been randomized, a maximum of eight kits would have been shipped to the sites and only two would have been used. The number of kits wasted would be six, which would be much lower than the 14 kits under the traditional approach in the earlier example. The percentage of wastage would

be 37.5% (6/16) vs. 87.5% (14/16). In addition to saving drug supply, the treatment would be balanced (one treatment A and one treatment B) by the central randomization capability of IVRS/IWRS although only two patients were enrolled. In traditional randomization, treatment balance across sites can happen only by chance, not by design.

In all of the examples given, the size of the study (i.e., number of patients and sites) is kept small for easy illustration and understanding. In real studies, the numbers of sites and patients are much larger, which generally would lead to a much greater saving in drug supply.

PATIENT RANDOMIZATION USING THE INTERACTIVE VOICE/WEB RESPONSE SYSTEM

In addition to the dynamic mapping of patient number, randomization code, drug assignment, and drug supply, IVRS/IWRS also performs stand-alone patient randomization for various randomization methods. The most commonly used

methods in clinical trials include nonstratified randomization, stratified randomization, and minimization. The implementation of these methods using the IVRS/IWRS is described next.

NONSTRATIFIED RANDOMIZATION

Whether it is a permuted-block or a simple randomization, the implementation is straightforward in a nonstratified randomization because it involves only one randomization schedule. The IVRS/IWRS, upon verification of the entry and the collection of patient eligibility, connects the patient to the next available treatment code in the randomization schedule.

This type of randomization is commonly used in randomized large-scale, open-label studies. Large-scale studies would have a greater chance of achieving treatment balance within a stratum because of sufficient number of patients enrolled in each stratum. In open-label trials, treatment assignment is known to both patient and investigator; therefore it is likely to be subject to selection bias (e.g., the investigator may choose to assign the active treatment rather than a placebo to a more severely ill patient). The IVRS/IWRS is especially valuable in these studies because the treatment is assigned at the moment when the phone call is completed or the web page information is submitted and therefore the selection bias is avoided.

STRATIFIED RANDOMIZATION

One of our earlier examples involved treatment balance within each study site. Study site is considered a stratification factor in this case because of potential “institution effect” in carrying out the trials. Many clinical trials, especially in cancer research, involve multiple prognostic factors that could affect treatment outcome. Traditionally, treatment balance within a stratum is achieved by generating a permuted-block randomization schedule for each stratum. All such schedules are stored in the IVRS/IWRS database. The IVRS/IWRS, upon collecting patient information, first matches the stratum and then searches for the next available randomization code in that stratum.

For example, in the treatment of stress incontinence, the baseline incontinence episode frequency (IEF) and gender are thought to have impact on the treatment outcome; therefore treatment balance within each stratum defined by baseline IEF and gender is deemed necessary. Because there are three levels of baseline IEF (mild, moderate, and severe) for each gender, a total of six baseline strata is considered for randomization. A randomization schedule is generated for each of the six strata, and all six schedules are stored in the IVRS/IWRS database.

When a site makes an entry to randomize a patient, IVRS/IWRS first collects the stratification information through the phone or the webpage. If the patient is female with moderate baseline IEF, IVRS/IWRS will search for the next available randomization code in the randomization schedule for the stratum of female with moderate baseline IEF, and will assign the corresponding treatment to that patient.

One difficulty of using this procedure is that the number of strata increases geometrically with the number of prognostic factors and their levels. For example, three prognostic factors, each with four levels, will generate 64 strata ($4 \times 4 \times 4$). As the number of strata increases, the ratio between the total number of patients and the number of strata becomes smaller. In other words, the number of patients in each stratum could be so small that in most strata the first permuted block of treatments would not be completely assigned. The result would be a considerable imbalance of treatment assignments across all stratification factors.

Although this procedure has traditionally been used, it does have limitations in balancing treatments simultaneously across several prognostic factors. Minimization procedures that overcome these difficulties have since been proposed by Taves^[1] and expanded by Pocock and Simon.^[2] The implementation of a minimization procedure by IVRS/IWRS is described and illustrated in an example in the next section. The manner in which stratification can be incorporated into the analysis needs to be determined prior to the use of this method.

MINIMIZATION

Minimization is a method of assigning patients to treatments in order to minimize the differences between the treatment groups in the number of patients as well as in patient characteristics and prognostic factors. Although the minimization method is mathematically straightforward, it had not been widely used for decades following its inception because of the difficulties in implementing it on a routine basis without an interactive computer. Therefore the introduction of IVRS/IWRS has made this dynamic procedure a popular one for clinical trials in recent years because it assigns treatment on an ongoing basis and does not require a prespecified randomization schedule. This procedure is best illustrated by the following example.

Suppose that a trial for controlling stress incontinence is conducted in five centers and that there are two treatment groups (active treatment and placebo) to be balanced with regard to baseline IEF, gender, and centers. A total of 93 patients has already been entered. The distribution of these patients by the three stratification factors is given in [Table 4](#). This table is stored in the IVRS/IWRS relational database. The IVRS/IWRS collects

Table 4 Number of Patients by Stratification Factors for the First 93 Patients

Stratification factor	Active	Placebo
Sex		
Male ^a	24	25
Female	23	21
Baseline IEF		
Mild	19	20
Moderate	20	19
Severe ^a	8	7
Site		
1 ^a	7	8
2	9	8
3	13	12
4	14	12
5	4	6

^aStrata for Patient 94.

the stratification factors associated with the next patient: Patient 94 is from site 1 and is a male with severe baseline IEF. For each treatment group, IVRS/IWRS adds up the number of patients who had already been randomized and who shared the same baseline characteristics as Patient 94 and assigns the patient to the group having the lower total.^[3] In this example, the sum for the active group is 39 (24 + 8 + 7) and for the placebo group is 40 (25 + 7 + 8). Therefore Patient 94 is assigned to the active group, thus minimizing the imbalance in the number of patients between the two treatment groups across all the stratification factors. Note that the marginal total is used for decision making in this example simply for easy illustration; other criteria for decision making can be found in other references.^[1,3]

In this example, Patient 94 is assigned to the active drug with a probability of 1. Alternatively, a less “deterministic” approach can be applied, which assigns the new patient to the treatment with a lower total with a probability of less than 1 (e.g., 0.75 or 0.95). For this type of randomization, IVRS/IWRS uses a uniform random-number generator to perform the task. Although the random numbers generated by a computer are in fact pseudorandom numbers, they are able to serve the purpose of randomization without compromising the integrity of the process. Let us extend our current example and assume that the probability is set at 0.80. A list of uniform random numbers, ranging from 0.00–0.99, is generated. The IVRS/IWRS searches the list for the next random number and assigns Patient 94 to active treatment if the next available random number is between 0.00 and 0.79, inclusively, and to placebo otherwise.

As a general practice, minimization should not be applied until a given number of patients has been randomized using a permuted-block design so that the risk of

revealing the treatment codes of the first few enrolled can be avoided.

OTHER INTERACTIVE VOICE RESPONSE SYSTEM APPLICATIONS

There are several additional capabilities of IVRS/IWRS besides randomization and drug management. One is the collection of real-time quality data in clinical trials. For example, the patient diary in clinical trials has been a cumbersome, handwritten process subject to human error and missing data. Using IVRS/IWRS, quality data can be obtained directly from the patient. The IVRS/IWRS can also remind the patient to enter the diary data so that missing data can be avoided, and a high patient compliance can also be expected. This has proven to be a major cost savings because of the ease of data processing as well as the accelerated availability of quality data.

In addition, in long-term-safety studies, IVRS/IWRS can collect and provide real-time crucial safety information, such as serious adverse events and mortality data. The fast and accurate information provided by IVRS/IWRS has proven to be valuable for monitoring the safety of clinical trials. Other operational aspects of clinical trials, such as patient enrollment and withdrawal status, can also be collected through IVRS/IWRS. This type of real-time data is very useful for strategic planning (e.g., enrollment may need to increase if the dropout rate is higher than expected in the protocol).

CONCLUSION

The interactive voice/web response system is an application based on the rapidly growing Internet and web-based system together with the computer telephony technology. Its multilingual capability and its ability to function without human intervention provide services at any time and place. The computer-based technology makes worldwide access possible, therefore making it an ideal tool for central randomization and drug management in clinical research. This entry has described the application of IVRS/IWRS in randomization and drug management. One of the great advantages of using IVRS/IWRS in managing the clinical drug supply is the reduction of drug wastage. Our example demonstrated a reduction in drug wastage from 87.5% under the traditional approach to 37.5% using IVRS/IWRS. In addition to saving drug supply, IVRS/IWRS has the ability to centrally randomize the patients from all sites so that treatment balance can be achieved across all sites for the entire study. The IVRS/IWRS technology can also provide clinical researchers with a new and cost-effective method for collecting real-time quality data and for providing critical monitoring information at any time and any place a digital phone or the Internet/web browser is available.

Japan: Ministry of Health, Labour and Welfare and Pharmaceutical Administration

Kiyohito Nakai

Ministry of Health, Labour and Welfare, Tokyo, Japan

Abstract

Under the MHLW, a wide range of affairs from clinical trials and approval review to measures for safety in the postmarketing stage is now handled to secure and improve the health and livelihood of people in Japan. This entry details the role of the MHLW in the lives of Japanese citizens and the Japanese pharmaceutical industry.

INTRODUCTION

Advances in science and technology and changes in domestic and international situations have made pharmaceutical affairs even more complicated. As the social needs and demands arose, the system of pharmaceutical administration in Japan has been dramatically changed in the last decade, including the amendment of the Pharmaceutical Affairs Laws in 1996 and the establishment of the Pharmaceutical and Medical Devices Evaluation Centre (PMDEC) under the National Institute of Health Science in 1997.

In January 2001, when the Japanese government carried out the reorganization of government ministries and agencies, the Ministry of Health and Welfare and the Ministry of Labour were merged to form the Ministry of Health, Labour and Welfare (MHLW). In the new system under the MHLW, a wide range of affairs from clinical trials and approval review to measures for safety in the postmarketing stage is now handled to secure and improve the health and livelihood of people in Japan.

MINISTRY OF HEALTH, LABOUR AND WELFARE

Function

In order to guarantee and improve the health and livelihood of the people, the MHLW is responsible for improving and promoting the social welfare, social security, public health, and the conditions and environment of labor. Furthermore, the MHLW is responsible for extending aid to the war repatriated, wounded, and sick soldiers

and the families of the war dead and nonrepatriated soldiers, and for settling pending affairs in the former army and navy.^[1]

Organization

As shown in [Fig. 1](#), the MHLW consists of the Minister's Secretariat, the Director General for Policy Planning and Evaluation, and 11 bureaus (the Health Policy Bureau; the Health Service Bureau; the Pharmaceutical and Medical Safety Bureau; the Labour Standards Bureau; the Employment Security Bureau; the Human Resources Development Bureau; the Equal Employment, Children and Families Bureau; the Social Welfare and War Victims' Relief Bureau; the Health and Welfare Bureau for the Elderly; the Health Insurance Bureau; and the Pension Bureau). Among the bureaus in the MHLW, the Pharmaceutical and Medical Safety Bureau (PMSB) and the Health Policy Bureau (HPB) are principally responsible for pharmaceutical administration.

A large number of establishments such as institutes, national hospitals, quarantine stations, and social welfare facilities are associated with the MHLW. The institutions and organizations of importance in pharmaceutical administration and regulation include the Pharmaceutical Affairs and Food Sanitation Council (PAFSC), the National Institute of Health Science (NIHS), and the National Institute of Infectious Diseases (NIID). In addition, the Organization for Pharmaceutical Safety and Research (OPSR), which is not an organization of the MHLW but a semigovernmental body, has a very important role in pharmaceutical administration and regulation.

Fig. 1 Organization of Ministry of Health, Labour and Welfare (Health-related organizations only)

ADMINISTRATIVE ORGANS RESPONSIBLE FOR PHARMACEUTICAL AFFAIRS

Pharmaceutical and Medical Safety Bureau

The PMSB was established in July 1997 to provide a stricter approval review system for drugs and to improve measures for safety of medical and pharmaceutical supplies and facilities. This bureau is composed of five divisions (the General Affairs Division, the Evaluation and Licensing Division, the Safety Division, the Compliance and Narcotic Division, and the Blood and Blood Products Division) and the Department of Food Sanitation. The PMSB is in charge of affairs regarding the quality and safety of drugs, quasi-drugs, cosmetics, medical devices,

and other health-related products; the safety management of medical facilities such as hospitals and clinics; and the control of narcotics, psychotropics, cannabis, opium, stimulants, and a variety of poisonous and deleterious substances.

Health Policy Bureau

The HPB is in charge of planning policies for the realization of a high-quality, effective system for offering medical services and is composed of seven divisions. Among the divisions of the HPB, the Economic Affairs Division and the Research and Development Division are involved in pharmaceutical affairs. These divisions are in charge of the management of the pharmacomedical supply system

and the planning of measures for research and development of drugs.

Pharmaceutical Affairs and Food Sanitation Council

The PAFSC is an advisory body to the Minister for Health and Welfare, consisting of specialists in fields such as medical, pharmaceutical and biological sciences, statistics, and social sciences. It is divided into two councils (the Pharmaceutical Affairs Council and the Food Sanitation Council), both of which are subdivided into several committees and their subcommittees. The PAFSC conducts the investigation into and consideration with regard to pharmaceutical affairs and food sanitation, at the request of the Minister for Health, Labour and Welfare, including revision of the Japanese Pharmacopoeia, establishment of standards for pharmaceuticals, and the approval of new drug and medical devices.

National Institute of Health Sciences

The NIHS, formerly called the National Institute of Hygienic Sciences, is responsible for conducting basic research to ensure the quality, efficacy, and safety of a wide range of products that directly and indirectly affect the human health. To ensure the policies of the MHLW that reflect the results of such research, NIHS fulfills its mission of improving the quality of life of Japan's citizens.

Pharmaceutical and Medical Evaluation Centre

Under the NIHS, the PMDEC was established in 1997. PMDEC has a very important role in the Japanese pharmaceutical administration system, especially for new drug-approval procedures. The PMDEC is in charge of reviewing approval applicants such as drugs, quasi-drugs, cosmetics, and medical devices and conducting the reexamination and reevaluation of drugs and medical devices. In the review procedure in the PMDEC, review teams are organized from experts in such fields as medicine, pharmacology, veterinary science, and statistics and perform an approval review of applicants.

National Institute of Infectious Diseases

The NIID was formerly the National Institute of Health. This institute mainly conducts researches on the pathogenicity, etiology, prevention, and treatment of infectious diseases. In addition, the NIID is involved in researches and examinations and establishes the standard of biological products such as vaccines and blood products.

Organization for Pharmaceutical Safety and Research

The OPSR^a was established in 1979 as a semigovernmental body authorized by the Minister of Health and Welfare in accordance with the Law of the Organization for Pharmaceutical Safety and Research. Among the six departments of the OPSR, the Product Reviews Department, Clinical Trials Guidance Department, and Compliance Review Department are in charge of the consultation and reviews of clinical trials and investigations into the suitability of data with the reliability standards, GLP, GCP, and GPMSP, which are submitted with pharmaceutical affairs applications. These businesses are very closely connected with the process of drug approval under the commission of the MHLW and in accordance with the Pharmaceutical Affairs Law.

In addition to these businesses, the OPSR is responsible for reviewing equivalency between medicines applied for approval and medicines that have already been approved (equivalency review), providing prompt relief to individuals with health conditions such as disease and disablement, and death caused by adverse reactions when making proper use of a licensed drug, and for supporting the promotion of researches in pharmaceutical technology and orphan drug development.

PHARMACEUTICAL REGULATION IN JAPAN

Laws Related with Pharmaceutical Affairs

The administration of pharmaceutical affairs are regulated by several laws as follows: the Pharmaceutical Laws, the Pharmacists Laws, the Law of the Organization for Pharmaceutical Safety and Research, the Blood Collection and Blood Donation Services Control Law, the Poisonous and Deleterious Substances Control Law, the Narcotics and Psychotropics Law, the Cannabis Control Law, the Opium Law, and the Stimulants Control Law. Among these laws, the Pharmaceutical Affairs Law provides fundamental regulations and schemes for pharmaceutical activities to ensure the quality, efficacy, and safety of drug and medical devices and also to promote R&D activities, especially for orphan drugs.

DRUG DEVELOPMENT

Development of a new drug is regulated and managed under several organizations including the PMSB in the MHLW, the

^aThe PMDEC and OPSR will be merged and a new organization will be established by April 2004 as part of a reorganization of the Japanese pharmaceutical administration system.

PMDEC under NIHS, the OPSR, and the PAFSC. It can be divided into three stages: the clinical trial stage, the approval stage and the postapproval stage. A summary of the measures to ensure the safety and quality of the drugs in each stage of the drug development process is shown in Fig. 2.

Clinical and Nonclinical Studies of Drugs

A developed drug undergoes several nonclinical studies such as physiological studies, toxicity studies in accordance with the Standards for Conduct of Nonclinical Studies on the Safety of Drugs [also called good laboratory practice (GLP)], and pharmacological and pharmacokinetic studies until notification of clinical trials is submitted to the MHLW. The clinical trials in the premarketing stage, divided into Phase I, Phase II and Phase III studies, must be in accordance with the Standards for Conduct of Clinical Trials [also called good clinical practice (GCP)].

Consultation of Clinical Trials

A company that tries to get an approval in Japan can ask for advice on clinical trials from OPSR, which is supported by PMDEC and PAFSC. The OPSR provides four kinds of advice, such as pre-first clinical trial notification advice, end of Phase 2 advice, preapproval application advice, and individual advice.

A company requests advice on the clinical trial and provides related data. The OPSR gives an advice to the company, and delivers the minutes of the meeting that shows the discussion between the OPSR and the company. The

company can use the minutes as a part of the documents for drug application. A flowchart of consultation of clinical trials is shown in Fig. 3.

Review of Clinical Trial Design

When a product under investigation is intended to be used in humans for the first time in Japan, the sponsor has to submit a clinical-trial notification to the PMDEC 30 days before the trial starts. The PMDEC sends the notification to the OPSR. The OPSR discusses with the sponsor and reviews the notification from the point of view of safety and the protection and well-being of human subjects involved in the trials.

Drug Approval

For manufacturing and importing drugs in Japan, an approval is necessary from the Minister for Health, Labour and Welfare. The general process of drug approval is shown in Fig. 4.

According to the Pharmaceutical Affairs Law, data concerning a drug intended to be manufactured/imported is required to be submitted to the PMDEC. The data must comply with the standards specified in the ordinances of the MHLW such as the GLP, the GCP, and the Standards for the Reliability of Application Data. Drugs are classified into “prescription drugs” and “nonprescription drugs,” both of which are divided into those with new ingredients and those with already approved ingredients. From the data submitted by an applicant, each of the drugs

Fig. 2 Development of drugs. Drug development is divided into three stages (clinical trial stage, approval stage, and postapproval stage), throughout which the safety and quality of a new drug are regulated

Fig. 3 Consultation of clinical trials

applied for approval is examined in detail with regard to its quality, efficacy, and safety by a team of specialists in the PMDEC, and after it is reviewed whether or not it has complied with the reliability standards, GLP and GCP, by the OPSR. After completion of the team review, the application is investigated and discussed by the committee and the pharmaceutical affairs council of the PAFSC. Finally, decisions for approval of drugs is made by the MHLW. The applicant receives an approval after these procedures are completed.

In addition to the approval of drug, the license to manufacture/import the drug is necessary for the company that tries to manufacture/import the drug. The license is examined when the application comes through whether or not the applicant is qualified for the manufacture/importation of the drug regarding their facilities and personnel, in compliance with the Regulations for Manufacturing Control and Quality Control of drugs [also called good manufacturing practice (GMP)] by the prefectural government or the Minister for Health and Welfare.

In general, the periods required for an approval of prescription drugs, nonprescription drugs, and drugs used for in vitro diagnostic tests, shortened from April 2000, are 12, 10, and 6 months, respectively.

POSTMARKETING SURVEILLANCE OF DRUGS

To assure the quality, efficacy, and safety of drugs, all approved drugs are kept under surveillance after coming into the market. The Good Post-Marketing Surveillance Practice (GPMSP) is applied as a standard for the proper implementation and reliability of the postmarketing

surveillance data. The GPMSP embodies the provisions to which pharmaceutical companies such as manufacturers and importers are subject in the organization and management of postmarketing surveillance. The measures in the postapproval stage are classified into the reexamination system, the reevaluation system, and the adverse drug reaction (ADR) reporting system (Fig. 2).

Reexamination System

Because of limitations on the data by premarketing clinical trials (referred to as Phase I/II/III studies) submitted for review at the time of approval of a new drug, the new drugs on the market are further examined for reconfirmation of the safety of drugs in practical use during the period of 4–10 years after their approval. The postmarketing reexaminations (referred to as Phase IV study) are obligatory for pharmaceutical companies that obtained approval of a new drug. The data of reexaminations submitted by pharmaceutical companies are reviewed by the PMDEC, and a final decision regarding the drug in question is made by the MHLW.

Reevaluation System

The reevaluation of drugs is performed systematically and periodically as already approved drugs in need of reconsideration according to the current status of the medical and pharmaceutical sciences. In addition to the periodic reevaluation system, an ad hoc reevaluation can be designed, for example, when the safety of drugs showing a certain efficacy becomes a subject of discussion.

Fig. 4 Process of drug approval. Pref Gov Prefectural Government; PAFSC: The Pharmaceutical Affairs and Food Sanitation Council; PMDEC: The Pharmaceuticals and Medical Devices Evaluation Centre; MHLW: The Ministry of Health, Labour and Welfare; OPSR: The Organization for Pharmaceutical Safety and Research; GCP: Good Clinical Practice

Adverse Drug Reaction Reporting System

The adverse drug reaction reporting system is the program for collecting and reporting information on the cases of any suspected adverse drug reactions and infections as a result of the use of drugs, including death, disability, disease, and congenital abnormalities. This reporting system is composed from pharmaceutical companies' reports under the Pharmaceutical Affairs Laws and with all medical facilities and pharmacies as monitoring facilities. The information on drug safety is also exchanged with various countries by the World Health Organization (WHO) International Drug Monitoring Programme.

SUPPLY OF DRUG INFORMATION

The information on the quality, efficacy, and safety of drugs provided by the postmarketing surveillance is reflected in some administrative measures taken by the MHLW, including suspension of manufacture and/or marketing of the drug in question, revocation of its approval, partial changes in the medication, and revision of its precautions. In addition, the information on drug safety is fed back from the MHLW to the people involved in medical and pharmaceutical services such as doctors, dentists, and pharmacists. It is also supplied in the form of a package insert leaflet or a drug safety report for emergency, termed doctor letter by pharmaceutical companies.

INTERNATIONAL HARMONIZATION IN DRUG DEVELOPMENT

To speed up the process of supplying excellent drugs developed in the world to the patients, it is essential to avoid unnecessary duplicate studies of drugs for their quality, efficacy, and safety. Achieving this goal will not only make approval review faster and efficient but also promote research and development, and urgent measures are required to realize this objective.

Under such circumstances, Japan, the United States, and the European Union (EU) have organized the International Conference of Harmonization of Technical Requirements for Registration of Pharmaceutical for Human Use (ICH) with a view to the harmonization of quality, efficacy, and safety requirements as the main topics, based on cooperation with the respective regulatory agencies and pharmaceutical industry associations. The MHLW is one of the members of the ICH Steering Committee that designs the topics of the ICH.^[2,3]

As results of harmonization of the requirements for registration progress in the ICH, the mutual acceptance of the data is increased. Actually, the clinical and nonclinical data from the United States or EU have been used as data for new drug application in Japan. Therefore, ICH guidelines have contributed to speeding up the drug development process in Japan. Furthermore, it is expected that clinical and nonclinical data that are collected from research and development processes in Japan would be more widely used in the United States or EU.

An agreement was reached on guidelines for the acceptance of data from foreign clinical studies as a result of ICH. In Japan, several guidelines related to this topic were issued. According to the guideline, when data from clinical trials performed in a foreign country are used, first the data are checked to assure that they comply with Japanese regular requirements, and then reviewed regarding whether the drug is affected by ethnic factors or not. When necessary, a bridging study is performed, and when it is concluded that the outcome of clinical study in the foreign country can be extrapolated to the Japanese population, the foreign data can be accepted. In these procedures for acceptance of data from foreign countries, the importance of consultation for clinical trials, which is conducted by the OPSR, is increased.

STATISTICAL PROGRAMS IN DRUG DEVELOPMENT

In March 1992, the MHLW published the guideline for statistical analysis of clinical studies, which shows examples of statistical misusing methods and indicate the most appropriate methods at that time.^[4,5]

The ICH guideline "Statistical consideration in the design of clinical trials" was published in November 1998

to replace the former guideline mentioned above.^[6] This guideline is intended to minimize the bias from the results of clinical trials and to maximize the precision of clinical trial data by proposing approaches. The guideline states that the actual responsibility for all statistical work related to a clinical trial should be done by statisticians who have appropriate qualifications and experiences. The participation of statisticians is intended to verify if the statistical principles have been appropriately applied in the trial to support drug development with other clinical trial experts. It also noted the importance of the statisticians' participation in the clinical trial from the stage of planning the trial and emphasized that the prespecification of protocol such as a documentation of the method of analysis is needed.

In addition to the ICH guideline, "Question & answer related to the guideline" is also issued as an attachment to the ICH guideline, with the objective of supporting the understanding of the guideline. It contains details that are not mentioned in the guideline. For example, it is clearly mentioned that 2.5% significance is used in the one-sided test and 5% significance is used in the two-sided test. It also mentions that several centers with a large number of subjects per center are preferable to a large number of centers with few subjects per center. It is difficult to say how many subjects are needed per center because the number of subjects depends on the target diseases and the treatment; however, 10 subjects per center are described in it as one example.

Kaplan–Meier Estimator

Hongyu Jiang

Harvard University, Boston, Massachusetts, U.S.A.

Jason Fine

University of Wisconsin–Madison, Madison, Wisconsin, U.S.A.

Abstract

The Kaplan–Meier is a nonparametric estimator of distribution function of a time to event variable in the presence of independent censoring. This entry provides the method of formulation for the estimator and addresses its relation to other estimators, and gives an example to illustrate the methodology.

INTRODUCTION

The Kaplan–Meier^[1] is a nonparametric estimator of distribution function of a time to event variable in the presence of independent censoring. The estimator is also referred to as the Product-Limit estimator because it was first derived as the limiting case of the classical life table estimator of Böhmer^[2] in the actuarial science literature for grouped data. However, the Product-Limit principle was not well known until Kaplan and Meier derived it using the maximum likelihood arguments in 1958.^[1]

In medical studies, time to a particular event is often used as a marker of the intervention effect. For example, in lung cancer clinical trial, time from start of treatment to death is often used to evaluate whether new therapy is superior to the standard treatment in prolonging survival. In HIV clinical trials, a frequently used endpoint in comparing antiretroviral treatments is time from start of treatment to viral rebound.^[3] The event of interest may be a marker of disease progression and is sometimes referred to as a surrogate endpoint for the failure time.^[4] In a randomized trial, event times are assumed to be independently distributed, where event times under different treatments may follow different distributions. By estimating the survival distributions in the treatment arms, one may gain insight into the treatment effect.

FORMULATION OF THE ESTIMATOR

To fix the notation, let T denote the event time variable. Let $\{T_i, i = 1, \dots, n\}$ denote the independent event times from n subjects whose common survival function $S(t) = \Pr(T > t)$ is of interest. If all event times are observed, the nonparametric estimate of the survival function is simply the empirical estimator, $\hat{S}(t) = \sum_{i=1}^n I\{T_i > t\}/n$. An advantage of the nonparametric estimator is that no assumption is

needed with respect to the underlying distribution. Parametric alternatives based on the Weibull distributions may lead to biased estimation of $S(t)$.

Fortunately, observing event times on all subjects is not realistic in most medical studies because of limited follow-up time. This results in right censoring, where the event time is only observed if it occurs before the end of follow-up, otherwise, it is censored and known to be larger than the last follow-up time, the so-called censoring time. Denote the censoring variable by C , assumed to be independent of T . Let the minimum of T and C be X . The observed data for the i th subject is X_i and $D_i = I\{T_i \leq C_i\}$, where $I\{\cdot\}$ is the indicator function. By convention, if T_i and C_i have the same value, then T_i is observed.

Notice that the times $\{X_i, i = 1, \dots, n\}$ may have ties. Let $t_1 < t_2 < \dots < t_m$ be the m ordered, unique event times, d_j be the number of subjects who have events at time t_j , and r_j be the number of subjects who have not experienced events before time t_j , i.e., at risk at t_j , where $j = 1, \dots, m$. One can easily verify that

$$d_j = \sum_{i=1}^n I\{X_i = t_j \text{ and } D_i = 1\} \text{ and} \\ r_j = \sum_{i=1}^n I\{X_i \geq t_j\}$$

The Kaplan–Meier estimator of $S(t)$ is defined on the range of the observed data, $[0, \tau_n]$, where $\tau_n = \max(X_i, i = 1, \dots, n)$:

$$\hat{S}(t) = \begin{cases} 1 & \text{if } t < t_1 \\ \prod_{j: t_j \leq t} \left(1 - \frac{d_j}{r_j}\right) & \text{if } t_1 \leq t \leq \tau_n \end{cases} \quad (1)$$

For $t > \tau_n$, if there is no censoring at the largest observed time τ_n , then $\hat{S}(t) = 0$, otherwise, $\hat{S}(t)$ is undefined. Efron^[5]

proposed estimating $S(t)$ beyond τ_n by 0, while Gill^[6] suggested $\hat{S}(\tau_n)$. The versions are equivalent in large samples. Klein^[7] showed that in small samples, Gill's estimator has smaller bias in the tail of the distribution.

As with the empirical distribution function, the Kaplan–Meier estimator is a step function. However, it only jumps at uncensored X_i . If there is no censoring ($\sum_{i=1}^n D_i = n$), then the estimator reduces to exactly the empirical estimator.

RELATION TO OTHER ESTIMATORS

The standard approach to deriving the Kaplan–Meier estimator is by maximizing the generalized (or nonparametric) likelihood.^[1,8–10] It is the limit of the life table estimator and has close connections with some other well-known nonparametric estimators for the distribution function with censored data.

Nelson–Aalen Estimator

Instead of estimating the survival function, the Nelson–Aalen estimator^[11,12] estimates the cumulative hazard function $H(t) = -\ln[S(t)]$ by

$$\hat{H}(t) = \sum_{j: t_j \leq t} \frac{d_j}{r_j}$$

where d_j/r_j may be viewed as an estimate of the instantaneous hazard function, $dH(t)/dt$, at time t_j . Although it is not a consistent estimate of $dH(t_j)/dt$, the sum of all such estimates for $t_j \leq t$ is consistent for $H(t)$. An alternative estimator of $S(t)$ can be obtained as $\tilde{S}(t) = \exp[-\hat{H}(t)]$. The equivalence between $\tilde{S}(t)$ and $\hat{S}(t)$ in large samples can be roughly illustrated as follows. From Eq. 1, $\hat{S}(t)$ may be written as

$$\hat{S}(t) = \exp \left[\sum_{j: t_j \leq t} \ln \left(1 - \frac{d_j}{r_j} \right) \right]$$

For large n , d_j/r_j is small for all t_j . Hence $\ln(1 - d_j/r_j) \approx -d_j/r_j$. It follows that $\hat{S}(t) \approx \tilde{S}(t)$. A more rigorous derivation shows that the Kaplan–Meier estimator and the Nelson–Aalen estimator are related through the product integral expression:

$$\hat{S}(t) = \prod_{u \leq t} [1 - d\hat{H}(u)]$$

Self-Consistent Estimator

The self-consistent estimator was first proposed by Efron^[5] for right-censored data. To estimate the survival function, a self-consistency equation is constructed analogously to that for the empirical estimator without censoring. In a

sample with size n , we estimate the survival probability at t by counting the number of subjects not experiencing the event by t and divide this number by n . Each subject whose event time is beyond t is counted as 1. A subject censored at a time x before t has $S(t)/S(x)$ chance of not failing by t and is counted as that fraction. The resulting self-consistent estimating equation is

$$S(t) = \frac{1}{n} \left(\sum_{i=1}^n I\{X_i > t\} + (1 - D_i) \sum_{i=1}^n \frac{S(t)}{S(X_i)} \right) \quad (2)$$

It has been shown that Efron's^[5] version of the Kaplan–Meier estimator is the unique solution to the above equation. The self-consistent estimating Eq. 2 can be used to derive an iterative procedure which is a special case of the EM algorithm for estimating the survival function. This idea has been generalized to construct nonparametric estimators from complicated censored, truncated, and grouped data^[13] which reduce to the Kaplan–Meier estimator in the special case of right censoring.

The self-consistent estimator may be interpreted via a redistribute-to-the-right algorithm, also proposed by Efron.^[5] The algorithm starts with an empirical estimator that puts probability mass $1/n$ at each observed time. Iterating from the smallest censored X_i to the largest censored X_i , the mass is removed and redistributed in equal portions to all points to the right of the censored time. With a finite sample, this algorithm converges to Efron's version of the Kaplan–Meier estimator.

INFERENCE ON SURVIVAL FUNCTION

Variance Estimation

The variance of the Kaplan–Meier estimator at time t , $\sigma^2(t)$, can be estimated by Greenwood's formula:^[14]

$$\hat{\sigma}^2(t) = \hat{S}(t)^2 \sum_{j: t_j \leq t} \frac{d_j}{r_j(r_j - d_j)} \quad (3)$$

When there is no censoring in the data, Eq. 3 reduces to the standard binomial variance estimator, $n^{-1}\hat{S}(t)[1 - \hat{S}(t)]$, for the empirical distribution. An alternative way of estimating the variance of $\hat{S}(t)$ is proposed by Aalen and Johansen:^[15]

$$\tilde{\sigma}^2(t) = \hat{S}(t)^2 \sum_{j: t_j \leq t} \frac{d_j}{r_j^2}$$

Klein showed that both variance estimators tend to underestimate the true variance of the Kaplan–Meier estimator for small to moderate samples. On average, Greenwood's formula tends to have smaller bias. A more conservative variance estimator is proposed by Peto et al.^[16]

Confidence Limits and Bands

In large samples, $\hat{S}(t)$ is approximately normally distributed with variance $\sigma^2(t)$. Hence a $100(1 - \alpha)\%$ pointwise confidence interval of $S(t)$ is

$$\hat{S}(t) \pm Z_{\alpha/2} \hat{\sigma}(t) \quad (4)$$

where $Z_{\alpha/2}$ is the $(1 - \alpha/2)$ th quantile of the standard normal distribution. However, the normal approximation to the distribution of $\hat{S}(t)$ may not work well in small samples, resulting in coverage probability much smaller than $(1 - \alpha)$. To achieve coverage closer to the nominal probability, we may construct confidence intervals for transformed $S(t)$ and then transform back. Two choices of transformation were suggested by Borgan and Liestøl.^[17] One is the log-minus-log transformation, $\ln\{-\ln[S(t)]\}$, and the resulting confidence interval for $S(t)$ is

$$\left[\hat{S}(t)^{\exp\left\{\frac{Z_{\alpha/2}\hat{\sigma}(t)}{\hat{S}(t)\ln\hat{S}(t)}\right\}}, \hat{S}(t)^{\exp\left\{-\frac{Z_{\alpha/2}\hat{\sigma}(t)}{\hat{S}(t)\ln\hat{S}(t)}\right\}} \right]$$

The other is the arcsine-square-root transformation, $\arcsin(S(t)^{1/2})$, and the corresponding confidence interval for $S(t)$ is

$$\left[\sin^2 \left\{ \max(0, \arcsin(\hat{S}(t)^{1/2}) - 0.5Z_{\alpha/2} \frac{\hat{\sigma}(t)}{(\hat{S}(t)(1 - \hat{S}(t))^{1/2})} \right\}, \sin^2 \left\{ \min\left(\frac{\pi}{2}, \arcsin(\hat{S}(t)^{1/2})\right) + 0.5Z_{\alpha/2} \frac{\hat{\sigma}(t)}{(\hat{S}(t)(1 - \hat{S}(t))^{1/2})} \right\} \right]$$

Besides normal approximation, confidence limits may also be obtained by inverting a likelihood ratio statistic,^[18] which also achieves good coverage probability in small samples, but may be computationally demanding.

With pointwise confidence intervals, we are able to make inference about survival probability at a single time point. Sometimes, however, it may be of interest to study the simultaneous behavior of the survival curve over an interval, say $[t_L, t_U]$. That is, we may want to find upper and lower confidence bands such that $\{S(t), t \in [t_L, t_U]\}$ is guaranteed to lay entirely within the bands with $1 - \alpha$ level of confidence. Statistically, we want to specify two random functions $L(t)$ and $U(t)$ satisfying

$$\Pr(L(t) \leq S(t) \leq U(t), \text{ for } t \in [t_L, t_U]) = 1 - \alpha \quad (5)$$

Because it can be shown that $\sqrt{n}\{\hat{S}(t) - S(t)\}$ converges weakly to a mean-zero Gaussian process with a simple Brownian motion structure,^[6,19] simultaneous inference on $S(t)$ over an interval is possible analytically. Two types of confidence bands have been proposed.

The first is equal precision (EP) bands which are proportional to the pointwise confidence limits at all t .^[20]

The width of each pointwise confidence interval for $S(t)$ (or transformed $S(t)$) on the interval $[t_L, t_U]$ is inflated by a constant κ such that the new limits satisfy Eq. 5. The value κ is determined by the sample size, the estimated survival probabilities and the estimated variances at t_L and t_U . A minor restriction is that the EP bands can only be obtained on a subinterval of $[t_L, t_U]$, where t_l and t_m are as defined previously. With moderate sample sizes, the non-transformed EP bands achieve coverage probability that is much lower than the nominal level, but the problem can be solved by constructing transformed EP bands.

Another method was developed by Hall and Wellner (HW).^[21] The HW bands inflate the pointwise confidence limits by factors that depend not only on the sample size, and the point and variance estimates of $S(t_L)$ and $S(t_U)$, but also on the point and variance estimates of $S(t)$. Hence the bands are not proportional to the pointwise confidence limits. Typically, HW bands are tighter than EP bands. Both nontransformed and transformed HW bands yield close to the nominal coverage probability.

The inflation coefficients for both EP and HW confidence bands are tabulated in Ref. [22], pp. 439–456.

AN EXAMPLE

A data set from an acute leukemia clinical trial^[23] will be used to illustrate the methodology. In the study, 21 pairs of children with acute leukemia matched by remission status were accrued. In each pair, one child was randomly assigned to the drug 6-mercaptopurine (6-MP) and the other to the control treatment. Patients were followed from randomization until their leukemia returned (relapse) or until the end of the study. The following are the observed ordered survival times (in weeks) where a superscript + means the observed time is a censored time.

6-MP arm:	6, 6, 6 ⁺ , 6 ⁺ , 7, 9 ⁺ , 10, 10 ⁺ , 11 ⁺ , 13, 16, 17 ⁺ , 19 ⁺ , 20 ⁺ , 22, 23, 25 ⁺ , 32 ⁺ , 32 ⁺ , 34 ⁺ , 35 ⁺ ;
Control arm:	1, 1, 2, 2, 3, 4, 4, 5, 5, 8, 8, 8, 8, 11, 11, 12, 12, 15, 17, 22, 23.

Let S_1 and S_2 denote the survival functions of subjects in the 6-MP arm and in the control arm, respectively. Because there is no censoring in the control arm, the Kaplan–Meier estimator of S_2 is just the empirical estimator. The more complicated computation of the Kaplan–Meier estimator of S_1 is illustrated in Table 1.

The estimates of the survival curves of time to relapse for the two arms are plotted in Fig. 1. The thick solid line is the Kaplan–Meier estimator of the survival function for the 6-MP arm, and the thin solid lines are the pointwise upper and lower 95% confidence intervals based on the log-minus-log transformation. Similarly, the thick dotted

Distinct event times: t_j	Number of events at t_j : d_j	Number at risk at t_j : r_j	Kaplan–Meier estimator $\hat{S}_1$	Greenwood variance estimator $\hat{\sigma}^2(\hat{S}_1)$
6	3	21	$[1 - (3/21)] = 0.857$	$0.857^2[3/(21 \times 18)] = 0.0058$
7	1	17	$0.857[1 - (1/17)] = 0.807$	$0.807^2[0.0079 + (1/(17 \times 16))] = 0.0076$
10	1	15	$0.807[1 - (1/15)] = 0.753$	$0.753^2[0.0116 + (1/(15 \times 14))] = 0.0093$
13	1	12	$0.753[1 - (1/12)] = 0.690$	$0.690^2[0.0164 + (1/(12 \times 11))] = 0.0114$
16	1	11	$0.690[1 - (1/11)] = 0.628$	$0.628^2[0.0240 + (1/(11 \times 10))] = 0.0130$
22	1	7	$0.628[1 - (1/7)] = 0.538$	$0.538^2[0.0330 + (1/(7 \times 6))] = 0.0164$
23	1	6	$0.538[1 - (1/6)] = 0.448$	$0.448^2[0.0569 + (1/(6 \times 5))] = 0.0181$

**Fig. 1** Comparison of survival curves of time to relapse by treatment arms

line and the thin dotted lines are the Kaplan–Meier estimate and its pointwise confidence limits, respectively, for the control arm. It is easy to see that the patients receiving 6-MP treatment have much higher survival probabilities than the patients receiving the control treatment.

OTHER ISSUES

Descriptive Statistics

The most commonly looked at summary statistic with censored data is the median, or 0.5 quantile of the distribution. Unlike the mean, it is less sensitive to the right tail of the survival distribution, where estimation may be unstable. The median survival time η can be estimated by

$$\hat{\eta} = \inf \{t : \hat{S}(t) \leq 0.5\}$$

In large samples, $\hat{\eta}$ is approximately normally distributed and the analytical form of its variance can be evaluated explicitly. However, variance estimation involves the density function of T at the median, which is difficult with censored data. To solve this problem, Brookmeyer and Crowley^[24] constructed confidence intervals for η by inverting the pivotal $(\hat{S}(\eta) - 0.5)$ without estimating the variance of $\hat{\eta}$.

The p th quantile of the survival distribution, η_p , can be similarly estimated by

$$\hat{\eta}_p = \inf \{t : \hat{S}(t) \leq 1 - p\}$$

Occasionally, the mean survival time (life expectancy), $\mu = \int_0^\infty S(t)dt$, may be of interest. However, μ cannot be reliably estimated with censored data when the support of T is larger than that of C . It is only possible to estimate the mean survival time restricted to an interval $[0, u]$, where u

is no bigger than τ_n , the largest observed time. The point and variance estimates of the restricted mean μ_u are:

$$\hat{\mu}_u = \int_0^u \hat{S}(t) dt;$$

$$\hat{\text{var}}(\hat{\mu}_u) = \sum_{j=1}^m \left[\int_{t_j}^u \hat{S}(t) dt \right]^2 \frac{d_j}{r_j(r_j - d_j)}$$

Hypothesis Testing

In the one-sample problem, testing whether the survival probability at a fixed time t_0 equals a hypothesized value b at α significance level is straightforward, simply by checking if b lays inside the $(1 - \alpha)$ confidence interval of $S(t_0)$. Testing whether a survival curve has a prespecified shape can be performed by checking whether it lies within the confidence bands. However, this approach tends to be conservative and is not widely used. For testing the hypothesis $H_0: S(t) = S_0(t)$, where $S_0(t)$ is a known continuous function, the standard approach is the logrank test for the equivalent hypothesis $H_0: \lambda(t) = \lambda_0(t)$, where $\lambda(t)$ and $\lambda_0(t)$ are the corresponding hazard functions defined as $\lambda(t) = -dS(t)/S(t)$ and $\lambda_0(t) = -dS_0(t)/S_0(t)$, respectively.^[25] Alternatively, the hypothesis can be tested using Cramér–von Mises-type or Kolmogorov–Smirnov-type test statistics based on the Kaplan–Meier estimator.^[25–27]

In the two-sample problem, the most commonly used test for comparing two continuous distribution functions is again the logrank test, which is most powerful if the proportional hazard alternative is true. However, when the proportional hazard assumption is violated, as occurs with crossing hazards, the logrank test may no longer be optimal. As in the one-sample case, two-sample Cramér–von Mises or Kolmogorov-type test statistics, which are sensitive to those alternatives, may be constructed using the Kaplan–Meier estimators.^[26,27] A study of the tests' small sample performance can be found in Ref. [28].

All the above-mentioned two-sample tests are rank-based. Another alternative approach is the so-called weighted Kaplan–Meier statistics, which is not a rank-based test, but is nonparametric. It reduces to a two-sample t -test for the equality of the mean survival times with uncensored data.^[29,30]

Informative Censoring

Random censoring is a necessary condition for the validity of the Kaplan–Meier estimator. That is, T and C are independent. In clinical trials with staggered accrual, subjects who have not experienced the event of interest by study closure have their event times right-censored at their total duration on study. This censoring is often referred to as

administrative censoring and is unlikely to be correlated to the outcome of interest. Thus the censoring time can be assumed to be independent or uninformative of the event time of interest. In other cases, the assumption may not be satisfied. Some patients may discontinue participation because of the reasons related to the unobserved failure time of interest. For example, patients may drop out of a study because the treatment is not working, e.g., they may be too sick to make the clinical visits. This is often referred to as informative dropout.

Care should be exercised when interpreting the estimated survival probabilities in the presence of potentially informative censoring because the Kaplan–Meier estimator may no longer be consistent. One way of dealing with this complication is by modeling the correlation between the failure time variable and the censoring variable, and then adjust the marginal estimate by the estimated dependence structure.^[31] The resulting estimator may be compared with the naive Kaplan–Meier curve, which is valid if T and C are, in fact, independent.

CONCLUSION

The Kaplan–Meier estimator is a simple but very useful nonparametric estimator of survival function with right-censored time-to-event data when the censoring is noninformative. Its large sample property and small sample performance have been thoroughly studied in literature. The estimation and graphical display of this estimator and its confidence interval or bands have been routine in analyzing right-censored failure time data.

Kappa Coefficients: Medical Research

Helena Chmura Kraemer

Stanford University School of Medicine, Stanford, Connecticut, U.S.A.

Abstract

A “kappa-type” statistic, generally, is one formed by linearly recalibrating some statistic to have the value zero when the data on which it is based are randomly generated. This entry discusses the mathematical basis for kappa coefficients in medical research and addresses some of the criticisms they face in terms of validity and reliability.

INTRODUCTION

A “kappa-type” statistic, generally, is one formed by linearly recalibrating some statistic to have the value zero when the data on which it is based are randomly generated, and one, when the generation is, in some sense, optimal. However, the kappa coefficients (population parameters) most commonly and usefully used in medical research are of only two types:

- Intraclass kappa, which is used to indicate the reproducibility, reliability, or precision of a binary clinical measure, such as presence/absence of a diagnosis, success/failure in response to treatment, positive/negative result of a medical test, or presence/absence of a risk factor.
- Weighted kappa, which is used to indicate the validity or accuracy of one such binary clinical measure assessed against a binary criterion or “gold standard.”

OVERVIEW

Kappa coefficients have had a checkered history. They have been “introduced” several times over, and the reasons for their continued use have little to do with the reasons for their introduction. Originally, they were introduced as percentage agreement corrected for chance, which only stimulated arguments about how “agreement” or “chance” should be defined, and whether such correction was at all necessary. Kappa coefficients have been applied not only to binary measures, but to more than two nonordered categories,^[1] to multiple diagnoses,^[2] as well as to ordered categories, with questionable success.

Theoretical papers have occasionally produced erroneous results, leading to Fleiss’s classic comment:^[3] “Many human endeavors have been cursed with repeated failures before final success is achieved. The scaling of Mount Everest is one example. The discovery of the Northwest

Passage is a second. The derivation of a correct standard error for kappa is a third.” (p. 974). Consequently, there are many papers in the research literature presenting questionable results in substantive as well as methodological areas, and predictably, papers questioning the use and value of kappa coefficients. Indeed, the introduction of kappa has been described as the major impediment to the development of high quality psychiatric diagnoses.^[4]

In the following discussion, the primary focus is on the types of kappa coefficients that have proved valuable in medical research, namely the intraclass and weighted kappas for binary measures. Then we will discuss how kappa fits within the context of other measures available for the same tasks. Finally, we will discuss some of the controversies surrounding kappa coefficients.

MATHEMATICAL BASIS

Let X_{sr} denote a binary random variable, for convenience one that takes on the values 1 and 0, that represents a binary classification of subject s ($s = 1, 2, \dots$) from a population of subjects, and r a rater or rating ($r = 1, 2, \dots$) from a population of possible or potential ratings. For subject s , the probability that a randomly selected rating will have $X_{sr} = 1$ is p_s , where p_s has some (usually unknown) distribution from 0 to 1 over the population of subjects. The population mean $E(p_s) = P$, the prevalence or incidence of whatever X indicates, and the population variance is σ_p^2 . The intraclass kappa is defined as:

$$\kappa_p = \sigma_p^2 / PP',$$

where $P' = 1 - P$.

For example, X_{sr} might be a diagnosis or a medical test result (positive = 1, negative = 0) for a disorder. Then, a very common simple mathematical model is one where it is assumed that the probability of having the disorder is π . Those who have the disorder have $p_s = \text{Se}$ (Se is a constant

“sensitivity”), and those without $p_s = 1 - \text{Sp}$ (Sp a constant “specificity”). This posits a two-point distribution for p_s that is particularly easy to work with. In this case:

$$\begin{aligned} P &= \pi \text{Se} + \pi'(1 - \text{Sp}), \quad \text{and} \\ \sigma_p^2 &= \pi\pi'(\text{Se} + \text{Sp} - 1)^2 \\ \kappa_p &= \pi\pi'(Se + Sp - 1)^2 / PP' \end{aligned}$$

Note that in this model, as π approaches either 0 or 1, κ_p approaches zero. This becomes important in some of the controversies surrounding kappa coefficients.

However, while mathematically convenient and useful for exploring insights about reliability or validity, such simple models seldom well represent real clinical applications. The distribution of p_s can be estimated by taking multiple independent measures for each subject using M randomly selected raters or ratings from the population of potential ratings for each subject. The proportion of positive ratings for subject s is an unbiased estimator of p_s . With a large enough sample of subjects, one can approximate the distribution of p_s from their sample estimates. When this has been done for either medical diagnoses or tests, it appears that p_s is more likely to have a continuous U-shaped distribution between 0 and 1, than, for example, the two-point distribution described above. That is, there are likely to be many subjects whose signs, symptoms, and response unambiguously indicate $X = 0$ ($p_s = 0$) or $X = 1$ ($p_s = 1$) to the rater, but p_s for the remaining subjects will range across the entire spectrum from 0 to 1. To make strong, but unwarranted, assumptions about the distribution of p_s in a model is problematic, and can seriously mislead. Kappa coefficients require no such strong assumptions.

THE INTRACLAS KAPPA: REPRODUCIBILITY OR RELIABILITY

Consider the problem of the “independent second opinion.” The probability that a randomly selected subject evaluated by two independent raters sampled from the population of raters will both be positive is $E(p_x^2) = P^2 + \sigma_p^2 = P^2 + \kappa_p PP'$. The probability that the two disagree is $2PP'(1 - \kappa_p)$, and the probability that both are negative is $P'^2 + \kappa_p PP'$. Then:

$$\begin{aligned} \kappa_p &= \text{Prob}(\text{second positive if first positive}) \\ &\quad - \text{Prob}(\text{second positive if first negative}) \end{aligned}$$

and

$$\begin{aligned} \kappa_p &= \text{Prob}(\text{second negative if first negative}) \\ &\quad - \text{Prob}(\text{second negative if first positive}) \end{aligned}$$

Thus when $\kappa_p = 0$, the first opinion has no predictive value for the second, whereas when $\kappa_p = 1$, the first always perfectly predicts the second. In general, κ_p quantitatively indicates how closely the first and second opinions will

agree, an interpretable measure of reproducibility of measurement.

Moreover, the “reliability” of a measure is classically defined as the percentage of the observed variance (here PP') representing true variance (here σ_p^2). Thus the definition of the intraclass kappa corresponds exactly to the classical definition of the reliability of a measure.

When $M = 2$, κ_p is particularly easy to estimate. If the proportion of the N subjects sampled on which both raters agree is A , and the proportion of all $2N$ ratings that are positive is $\hat{P}$ (an unbiased estimator of P), then the maximum likelihood estimator of κ_p is:

$$\begin{aligned} & (A - \hat{P}^2 - \hat{P}'^2) / (1 - \hat{P}^2 - \hat{P}'^2) \\ & \hat{P}' = 1 - \hat{P} \end{aligned}$$

Here the origins of kappa as the statistic percentage agreement (A) corrected for chance are clearly seen. While it is true that this was the original motivation for introduction of the sample kappa coefficient, the argument for the continued use of the intraclass kappa as a coefficient of reproducibility or reliability is not based on this computation, but (1) on its interpretability as a measure of the predictive value of a first measure for a second, and (2) that the intraclass kappa satisfies the classical definition of reliability of a measure. Finally, as we will see, intraclass kappa play an important role in influencing the precision of estimation of other parameters and in power of testing hypotheses.^[5]

Asymptotically, the variance of the intraclass kappa with two raters and N subjects is given by:^[6]

$$N \text{ variance} = (1 - \kappa_p) \left[(1 - \kappa_p)(1 - 2\kappa_p) + \frac{\kappa_p(2 - \kappa_p)}{2PP'} \right]$$

However, because the sample distribution of the estimator of intraclass kappa approaches a normal distribution very slowly (as is also true for the weighted kappa), it is recommended that either jackknife or bootstrap procedures be used to generate confidence interval or tests^[6] in preference to asymptotic theory.

When there are $M > 2$ raters/ratings, the same intraclass kappa can be estimated as follows: Let s be the number of positive ratings of the M given, and f_s the proportion of the N subjects with s positive ratings. Then:^[7]

$$\kappa_p = 1 - M \sum f_s(s/M)(1 - s/M)/(M - 1)\hat{P}\hat{P}'$$

where:

$$\hat{P} = \sum f_s s / M$$

While there are no fixed standards for what constitutes adequate reliability of measurement, useful “rules of thumb” have been suggested.^[8] A kappa greater than 0.8 is considered “almost perfect”; 0.61–0.8 as “substantial,”

0.41–0.6 as moderate; 0.2–0.41 as “fair,” and below 0.2 as “slight.” In fact, there are relatively few medical diagnoses that are “almost perfect,” the best are either “substantial” or “moderate” and many are only “fair.”^[9,10]

The reliability of a binary measure can almost always be improved with a little effort. One might standardize the protocols for testing, and the conditions of testing or measurement, to reduce the inconsistency of the subjects’ response. One might clarify the measurement protocol to raters, train the raters, and monitor their performance to reduce rater error.

If all else fails, one might use consensus ratings, i.e., one might have M raters per subject, and combine these M ratings into one. If one simply uses the number of positive ratings among the M ratings, one moves from a binary rating to an interval one. The kappa coefficient would not then be the appropriate reliability measure; the intraclass correlation coefficient would be a better choice.^[11–13] Then, the reliability of that interval measure would approximately follow the Spearman–Brown rule,^[14,15] where κ_p is the coefficient of reliability of a single binary rating,^[16] the reliability of a mean of M ordinal measures is approximately given by:

$$M\kappa_p / [1 + (M - 1)\kappa_p]$$

What this means is that if the reliability coefficient of a single binary rating is κ_p , but this is assumed inadequate, to raise the reliability of an interval consensus rating to R ; one would need approximately $R(1 - \kappa_p)/(1 - R)\kappa_p$ raters. Thus, for example, to raise the reliability from $\kappa_p = 0.4$ to $R = 0.8$, one would need $(0.8 \cdot 0.6)/(0.2 \cdot 0.4) = 6$ independent raters per subject.

The problem in medical applications is that to make decisions about inclusion/exclusion from studies, whether to treat or not, whether to hospitalize or not, an interval consensus does not well serve. One still needs a binary measure. A binary consensus measure of M raters can be generated by selecting a cut-point, J , and declaring a consensus result positive if J or more of the M raters are positive. How many raters (M) would be needed and what cut-point (J) should be used to achieve acceptable reliability is a difficult problem that can only be approached empirically.^[17,18] Intuitively, many feel that J should be just larger than $M/2$, i.e., the binary consensus of M raters should be positive if the majority agree that it is positive. Unfortunately, this is one of those occasions when intuition misleads, for this majority rule does not always yield the most reliable binary consensus for M raters. Neither does the unanimity rule, i.e., that the binary consensus is positive if all M raters agree it is positive, or that the binary consensus is negative if all M raters agree it is negative. The optimal cut-point depends strongly on the unknown distribution of p_s in the population, and can vary widely from one clinical situation to another.

Concern about the reliability of binary measures in medical research and practice is well founded. Unreliability of diagnosis, for example, means that when a patient seeks an independent second or third diagnosis, the diagnoses will not agree. That is, of course, of concern both to medical consumers and to their physicians for it increases the risk of poor clinical decision making and consequently, unnecessary, medical costs. In research applications, unreliability of measurement attenuates the precision of estimators and reduces the power of statistical tests. Thus, not only does poor reliability necessitate the use of much large samples than might otherwise be necessary to detect clinical effects, thereby increasing the cost of research studies, but even when such effects are detected, the size of effects may be attenuated, and the accuracy of their estimation poor.

WEIGHTED KAPPA: VALIDITY

Suppose now that there are two binary variables— X_{rs} , as defined above, is a “gold standard” or a binary criterion, and Y_{rs} , which is another binary variable that is to be “blindly” assessed against that “gold standard.” For example, Y may be a medical test result, or a diagnosis, or a risk factor, and X may be the presence/absence of the corresponding disorder. For subject s , the probability that a randomly selected rating will have $Y_{sr} = 1$ is q_s , where q_s has some (usually unknown) distribution from 0 to 1 over the population of subjects. The population mean $E(q_s) = Q$ the prevalence or incidence of whatever Y indicates, and the population variance is σ_p^2 . The intraclass kappa for Y is defined as $\kappa_q = \sigma_p^2/QQ'$, where $Q' = 1 - Q$.

Now the probability that both $X_{rs} = 1$ and $Y_{rs} = 1$ (a “true positive” result) is:

$$E(p_s q_s) = PQ + \rho(\kappa_p \kappa_q)^{1/2} (PP'QQ')^{1/2}$$

that $X_{rs} = 1$ and $Y_{rs} = 0$ (a “false negative”) is:

$$E(p_s (1 - q_s)) = PQ' - \rho(\kappa_p \kappa_q)^{1/2} (PP'QQ')^{1/2}$$

that $X_{rs} = 0$ and $Y_{rs} = 1$ (a “false positive”) is:

$$E((1 - p_s) q_s) = P'Q - \rho(\kappa_p \kappa_q)^{1/2} (PP'QQ')^{1/2}$$

and that both $X_{rs} = 0$ and $Y_{rs} = 0$ (a “true negative”) is:

$$E((1 - p_s)(1 - q_s)) = P'Q' + \rho(\kappa_p \kappa_q)^{1/2} (PP'QQ')^{1/2}$$

Here ρ is the product moment correlation coefficient between p_s and q_s , in the population sampled. It should be noted here that whether ρ approaches zero, or either κ_p or κ_q approaches zero, one achieves the same results—the association between X and Y will appear random. This

is why unreliability attenuates all effect sizes measuring association.

When a binary measure is evaluated against a criterion, the costs or medical consequences of a false positive and a false negative may not be the same. If, for example, one were considering breast self-examination to detect breast cancers, the primary concern would be false negatives, for a false negative might lead to a fatal delay in initiating treatment, while a false positive would mean only some unnecessary anxiety and an unnecessary trip to the doctor. On the other hand, with mammography to detect breast cancers, there would be much greater concern about false positives, for that might mean initiation of unnecessary surgical biopsy, hospitalization, anesthetization—that themselves would put a cancer-free patient at unnecessary cost and risk. Acknowledgment of such possibilities led to the proposal for the weighted kappa^[6,19] that determines where the clinical costs of using Y instead of X for decision making lies between using a random number generator and that when using X itself.

The weighted kappa has the form:^[6]

$$\kappa(r) = \rho\sigma_p\sigma_q / (PQ'r + P'Qr')$$

where r is an index ($0 \leq r \leq 1$, $r' = 1 - r$) reflecting the relative clinical importance of false negatives vs. false positives. When $r = 1$, all emphasis is placed on avoiding false negatives (as for a screening test); when $r = 0$, all emphasis is placed on avoiding false positives (as for a definitive medical test). The most common choice of weight is when $r = 1/2$, when equal emphasis is placed on avoiding both types of errors. This coefficient is easily estimated from a 2×2 table relating the binary measure to its binary criterion, where TP, TN, FP, and FN denote the observed proportion of true positives, true negatives, false positives, and false negatives, respectively,

$$\kappa(r) = (TP \cdot TN - FP \cdot FN) / (\hat{p}(1 - \hat{q})r + (1 - \hat{p})\hat{q}r')$$

When there is careful consideration of the relative importance of false positives and false negatives in a clinical research situation, the most common choice is $r = 1/2$. In fact, this choice of $r = 1/2$ is so common that $\kappa(1/2)$ is often referred to as “the” kappa coefficient, as if there were no others. Moreover, when $r = 1/2$, $\kappa(1/2)$ is often called “percentage agreement corrected for chance.” However, calling the situation when both X and Y equal 1 or both X and Y equal 0 “agreement” is a misnomer, because X and Y measure different things. Here “chance” means $PQ + P'Q'$, the probability that X and Y are both either 1 or 0 if a random number generator were used to assign a proportion P to have $X = 1$ and Q to have $Y = 1$. It should be emphasized that using $r = 1/2$ should reflect a decision about the relative importance of the two types of errors, not be an automatic choice, for that can only mislead medical decision making.

WEIGHTED KAPPA IN THE CONTEXT OF MEASURES OF 2×2 ASSOCIATION

Some of the reservations expressed about kappa coefficients simply relate to the fact that these are relatively new indices compared to other measures of 2×2 association such as Odds Ratio, risk ratios, risk differences, and the Phi coefficient. Researchers with experience in evaluating risk factors, or medical tests, or diagnoses have long realized that one can choose among the various traditional measures of 2×2 association and often pick one that makes the association seem weak, and another that makes the same association seem strong. Such arbitrariness leads to comments such as: “lies, damn lies, and statistics.” It also makes the introduction of yet new measures of 2×2 association such as kappas, which may introduce even more discrepancy, seem injudicious. However, introduction of the weighted kappas actually clarifies the situation.

Table 1 presents a 2×2 table representing the probabilities of the various outcomes of two binary measures in a population. Below the table are the definitions of a range of common measures of 2×2 association: weighted kappa, sensitivity, specificity, predictive values, risk ratios, risk differences, and Odds Ratio (where there are five mathematically equivalent definitions). They are not all similarly scaled. Phi, the risk differences, and the weighted kappas have value 0 for random decision making and 1 when there are no errors; the risk ratios and the Odds Ratio have value 1 for random decision making and are infinite when there are no errors. Sensitivity, specificity, and the predictive values do not have a fixed null value, but equal 1 when there are no errors. The scaling differences are one source of problems, for it is difficult, for example, to know whether Odds Ratio or risk ratios equal 10 are large (much larger than 1!) or small (much smaller than infinite!).

Table 1 also lists the relationship of each index to the weighted kappas. It can be readily seen that all the measures, except the Phi coefficient and the Odds Ratio, either directly (risk differences) or recalibrated (sensitivity, specificity, predictive values, risk ratios) equal a weighted kappa for some value of r . This eliminates most of the arbitrariness of 2×2 measures of association, because it clarifies that different relative importance attached to false positives and false negatives explains much of the inconsistencies between different measures of 2×2 association. The two exceptions are the Phi coefficient and the Odds Ratio.

The Phi coefficient poses little problem. If $\kappa(r) = 0$ for any r , then $\kappa(r) = 0$ for all r , and $\Phi = 0$. If there are no errors, $\kappa(r) = 1$ for all r , and $\Phi = 1$ as well. If $P = Q$, the $\kappa(r)$ is a constant $\kappa(\cdot)$ for all r , and $\Phi = \kappa(\cdot)$. In general, the Phi coefficient is the geometric mean of the extreme kappa coefficients, while $\kappa(1/2)$ is their harmonic mean. Thus, frequently, Φ and $\kappa(1/2)$ are approximately equal.

Table 1 2×2 Association and Definitions of Associated Terms, Measures of 2×2 Association and Correlation Coefficients

	$Y = 1$	$Y = 0$	
$X = 1$	True positive (TP)	False negative (FN)	$P = a + b$
$X = 0$	False positive (FP)	True negative (TN)	$P' = 1 - P = c + d$
	$Q = a + c$	$Q' = 1 - Q = b + d$	1.0
Weighted kappas (r = any value between 0 and 1):			
$\kappa(r) = (TP\ TN - FP\ FN) / (PQ'r + P'Qr')$, $r' = 1 - r$.			
Definitions:			
Phi = $(TP\ TN - FP\ FN) / (PP'QQ')^{1/2}$			
Sensitivity of Y to X (Se) = TP/P			
Specificity of Y to X (Sp) = TN/P'			
Predictive value of a :			
Positive test (PVP) = TP/Q			
Negative test (PVN) = TN/Q'			
Risk ratios:			
$RR_1 = Se / (1 - Sp)$			
$RR_2 = Sp / (1 - Se)$			
$RR_3 = PVP / (1 - PVN)$			
$RR_4 = PVN / (1 - PVP)$			
Risk differences:			
$RD_1 = Se + Sp - 1$			
$RD_2 = PVP + PVN - 1$			
Odds ratio:			
$OR = (TP\ TN) / (FP\ FN)$			
$= (Se\ Sp) / ((1 - Se)(1 - Sp))$			
$= (PVP\ PVN) / ((1 - PVP)(1 - PVN))$			
$= RR_1\ RR_2 = RR_3\ RR_4$			
Relationship to weighted kappas			
Phi = $(\kappa(0)\kappa(1))^{1/2}$			
$(Se - Q) / (1 - Q) = \kappa(1)$			
$(Sp - Q') / Q = \kappa(0)$			
$(PVP - P) / P' = \kappa(0)$			
$(PVN - P') / P = \kappa(1)$			
$(RR_1 - 1) / (RR_1 + P' / P) = \kappa(0)$			
$(RR_2 - 1) / (RR_2 + P / P') = \kappa(1)$			
$(RR_3 - 1) / (RR_3 + Q' / Q) = \kappa(1)$			
$(RR_4 - 1) / (RR_4 + Q / Q') = \kappa(0)$			
$RD_1 = \kappa(P')$			
$RD_2 = \kappa(Q)$			
$OR - 1 = (P'\kappa(1) + P\kappa(0)) / (PP'(1 - \kappa(0))(1 - \kappa(1)))$			
$= (Q\kappa(1) + Q'\kappa(0)) / (QQ'(1 - \kappa(0))(1 - \kappa(1)))$			

Among the other measures of 2×2 association, the Phi coefficient is particularly important, because the 2×2 chi square test is most commonly used to test the null hypothesis of association equals $N\phi^2$ and:

$$\phi^2 = \kappa(1)\kappa(0) = \rho^2(\kappa_p, \kappa_q)$$

From this, it is obvious that the power of the test to detect association depends on: 1) the association between the true values of X and Y (ρ) and 2) the reliabilities of measurement of X and of Y (κ_p and κ_q).

That leaves the Odds Ratio, where there is a serious problem. When there is random association between X and Y , $\kappa(r) = 0$ for all r ; Odds Ratio equal 1. Similarly, when there are no errors, neither false positives nor false negatives, then $\kappa(r) = 1$ for all r , and the Odds Ratio equals infinity. Thus far, there are no discrepancies. However, suppose there were no false negatives, but many false positives. Then $\kappa(1) = 1$, but $\kappa(r) < 1$ for $r \neq 1$, and Odds Ratio is infinite. That $\kappa(1) = 1$ here is logical because $r = 1$

indicates that only the absent false negatives are of clinical importance. Similarly, when there are no false positives, but there are false negatives, $\kappa(0) = 1$, and $\kappa(r) < 1$ for all $r \neq 0$, but once again Odds Ratio is infinite. Again, here $\kappa(0) = 1$ is logical because $r = 0$ indicates that only the absent false positives are of clinical importance. Thus the Odds Ratio is infinite if either kind of error is absent, even if absent error is the one that clinically matters little, and the kind of error that is present but ignored is the one that matters a great deal. This is troublesome for the use and interpretation of the Odds Ratio in situations when clinical decision making can be misled.

When $P = Q = 1/2$, all weighted kappas are equal, $\kappa(r) = \kappa(\cdot)$. Then $Y = (\sqrt{OR} - 1) / (\sqrt{OR} + 1)$ equals $\kappa(\cdot)$ (Y is called "Yule's Index"). Thus when $P = Q = 1/2$, $\kappa(\cdot) = 0.2, 0.4, 0.6, 0.8$ correspond to Odds Ratios of 2, 5, 16, 81. That an Odds Ratio of about 2 would be considered "slight" corresponds poorly to interpretations of the Odds Ratio in the research literature, where an Odds Ratio of 2 often generates considerable scientific interest. This begins to suggest that the standards used to assess the magnitude

of the Odds Ratio are much less demanding than those for assessing kappa coefficients.

When $P = Q \neq 1/2$, again all weighted kappas are equal, $\kappa(r) = \kappa(\cdot) = \text{Phi}$. Then

$$\text{OR} - 1 = \kappa(\cdot) / PP'(1 - \kappa(\cdot)^2)$$

and Yule's index is now larger than $\kappa(\cdot)$, actually approaching 1, whenever P approaches either 0 or 1. Thus, for example, when $P = Q = 0.01$ and $\kappa(\cdot) = 0.2$, Odds Ratio = 32.6, and Yule's Index = 0.702. The latter suggest very strong association when all the weighted kappas indicate slight association. Which is right?

Suppose, in this case, that Y were a medical test to detect a fatal condition that could be averted with aggressive treatment, where the treatment would be costly and risky, but would prevent death. Then for every 10,000 people, 100 would have the condition. Of the 100 who have the condition, 21 would be detected by the test, and the remaining 79 would die of the condition undetected. Those 21 would be aggressively treated and saved. Of the 9900 who do not have the condition, 9821 would test negative, and 79 positive. Those 79 would also be treated aggressively because they would be thought to have the condition, incurring the cost and risk of the treatment, totally unnecessarily. Of the 100 subjects treated, 79 are treated unnecessarily. Thus one benefits 21 patients and harms 79. If the test itself carried cost or risk, the remaining 9900 whose fate is unaffected by the test would also incur some harm. In that case, one would benefit 21 patients and harm 9979. The Odds Ratio here of 32.7 ($R = 0.70$) would seem overly enthusiastic, and $\kappa(\cdot) = 0.2$ more reasonable.

In general, when association is nonrandom and either P or Q is extreme (near 0 or 1), Odds Ratio tends to be very large, when all other measures of association, most particularly the weighted kappas, are much smaller. As illustrated above, when one examines the consequences of using Y instead of X in such cases, it is often clear that the Odds Ratio tends to exaggerate association.

Clearly, anything that improves the reliability of X or of Y will improve the validity of Y assessed against X , regardless of what measure is used. In addition, one might also implement some action that would change the value of Q , for the validity of Y assessed against X , whatever the value of r , depends on the relative size of P and Q . Frequently, binary Y is defined by some scales exceeding a cut-point, e.g., systolic blood pressure greater than 120 mm Hg, or smoking more than 1 cigarette per day, or scoring less than 100 on an IQ test. In such cases, one can negotiate the cut-point to achieve the optimal $\kappa(r)$ for whatever value of r is appropriate to the context. Generally, best results are obtained when r is near 1 if $Q > P$, when r is near 0 if $Q < P$, and when r is near 1/2 if Q is approximately equal to P .

PROBLEMS WITH KAPPA?

The Base Rate Problem

One recurrent issue is the so-called "base rate problem" with kappa coefficients, i.e., that both the intraclass kappa for fixed X and weighted kappas for a fixed X and Y change when applied to different populations (differing P). Such change is a fact, but why it is regarded as a problem specific to kappa coefficients is not clear. Every correlation coefficient, for example, is likely to change as one moves from one population to another.

The genesis of labeling this as a problem for kappa in particular seems to be based on the mistaken assumptions: 1) that the sensitivity and specificity of Y to X are fixed constants, that p_s for each subject is either a constant Se or a constant Sp ; and 2) that the "gold standard" is pure gold (perfect reliability). If these assumptions were true, then regardless of which subpopulation were sampled (whatever the value of P), the Odds Ratio would equal $(\text{Se} \cdot \text{Sp}) / ((1 - \text{Se})(1 - \text{Sp}))$, a fixed constant. However, as with the two-point model, kappa coefficients would vary from one population to another depending on the value of P . However, almost no "gold standards" used in medical research are pure gold, having perfect reliability. Furthermore, as pointed out earlier, the two-point distribution model seldom, if ever, holds. Consequently, Odds Ratio varies from one subpopulation to another, just like kappa coefficients and other measures of association.

Multicategory Kappa

When both intraclass and weighted kappas were introduced, a multicategory version was proposed, i.e., a kappa useful when there were more than two unordered categories (e.g., ethnic group, country of birth).^[19] Such kappas have proved problematic. For example, the intraclass kappa when there are $C > 2$ categories can be expressed as:^[16]

$$\kappa_{\text{mult}} = \sum P_c P'_c \kappa_c / \sum P_c P'_c$$

where P_c ($c = 1, 2, \dots, C$) is the prevalence of category c in the population, $P'_c = 1 = P_c$, and κ_c is the intraclass kappa for the binary measure $X_c = 1$ for all subjects in category c , and $X_c = 0$ otherwise. If there is one category with high kappa and its P_c is near 0.5 (to maximize $P_c P'_c$), even if all the other categories are completely indistinguishable from each other (κ'_c 's near zero), the multicategory kappa would be very high. This works in the other direction as well; the multicategory kappa may be very near zero even if all the categories (relatively rare ones) are perfectly distinguishable, and one common category is unreliable. Consequently, the multicategory kappa may be misleading because it attributes to the categorical measure, as a whole, a reliability that may only apply to one of its categories. For

this reason, it is preferable to examine the individual binary kappas (κ_c , $c = 1, 2, \dots, C$) in assessing the reliability of a multicategory measure, as well as the cross-classifications to understand where errors might occur and why, rather than to use the multicategory kappa.

Kappa for Ordered Categories

Kappa coefficients have also been used for ordered categories (i.e., ordinal measures with a small number of responses, such as 5-point scales). In addition to the problem with multiple unordered categories (cited above), use of kappa here ignores the ordinal nature of the data. It has been pointed out that if one assigns scores to the ordered categories, and uses as a weight in the weighted kappa the absolute difference between the scores, the weighted kappa is then equivalent to an intraclass correlation coefficient.^[11,20] In fact, it is some form of intraclass correlation coefficient that is preferable for use with ordinal measures over the use of any kappa coefficient.

Interchanging the Intraclass and Weighted Kappa Coefficients

Kirk and Kuchins^[4] blamed the “discovery” of the kappa coefficients [specifically $\kappa(1/2)$] for impeding the progress in developing psychiatric diagnosis. Their argument was that the emphasis that kappa coefficients place on reliability assessment obscured the much more important issue of the validity of diagnosis. In fact, while the intraclass kappa is a measure of reliability, the weighted kappa [e.g., $\kappa(1/2)$] is a measure of validity. Thus it is not kappa per se that distracted focus from validity. In fact, it was the realization that one cannot achieve validity unless one already has reasonable reliability. There was a judgment call that psychiatric diagnosis was not then yet reliable enough.

However, this type of misunderstanding has been quite common. In fact, $\kappa(1/2)$ is often inappropriately used as a measure of reliability, not validity. Only if the design of the study is such that $p_s = q_s$ for all subjects in the population, does $\kappa(1/2)$ estimate the same parameter as does the intraclass kappa, because then, $\rho = 1$, $\sigma_p = \sigma_q$, and $P = Q$. Even then, the sample estimate of $\kappa(1/2)$ would be less efficient than the sample estimate of intraclass kappa for the same population parameter.

In short, intraclass kappas and weighted kappas play different but interrelated roles in medical research applications, and the best coefficient should be chosen for each particular context in which it is to be used.

CONCLUSION

Intraclass and weighted kappas play important roles in medical research: intraclass kappa as a measure of

reproducibility or reliability, weighted kappas as unique measures of validity.

The major argument for the intraclass kappa as a measure of reliability is that it corresponds exactly with the classical definition of reliability, that it is easily interpretable clinically as well, and that it plays a recognizable role in the precision of parameter estimation and statistical hypothesis testing.

The uniqueness of the weighted kappa as a measure of validity lies in the weight that defines it, which reflects the relative clinical importance of false negatives to false positives in the context of application. It can be shown that most other measures of 2×2 association relate to one or another weighted kappa, thus clarifying that the discrepancies long noted between various measures of 2×2 association primarily relate to a choice of weights to false positives and false negatives, often a choice unknowingly made by the user. The major exception is the Odds Ratio, which often tends to exaggerate association.

It is true that kappa coefficients must move past their historical origins as “percentage agreement corrected for chance,” a description that ill characterizes what either kappa coefficient is designed to do. Moreover, many claims have been mistakenly made, either about kappa itself, or contrasts between other measures of association (Odds Ratio in particular) and kappa. Most important is the claim that Odds Ratio is constant over populations (untrue), while the kappa coefficients vary (true): the base-rate problem. In many cases, kappa coefficients have been misused, either for more than two categories, or for ordinal measures, or the intraclass kappa has been used in situations when the weighted kappa should have been used or the weighted kappa when the intraclass kappa should have been used.

Finally, the process of considering what relative weight to attach to false positives and to false negatives is not an easy one, nor one that clinicians, researchers, or policy-makers are accustomed to make. Nevertheless, the basis of medical decision making require such considerations so as to distinguish between accurate and inaccurate medical tests, to correctly identify risk factors for disorders, to identify those likely to respond to a treatment, and other similar tasks. Thus kappa coefficients are invaluable in the contexts for which they are designed—i.e., the reliability and validity of binary measures, particularly in the contexts of medical test evaluation, risk factor evaluation and evaluation of outcomes in randomized clinical trials.

Kruskal-Wallis Test for Ordered Categorical Data: Power Calculation

Chunpeng Fan and Donghui Zhang

Department of Biostatistics and Programming, Sanofi US Inc., Bridgewater, New Jersey, U.S.A.

Abstract

Although the Kruskal–Wallis test has been widely used to analyze ordered categorical data, power and sample size methods for this test have been investigated to a much lesser extent when the underlying multinomial distributions are unknown. This entry generalizes the power and sample size procedures proposed by Fan, Zhang, and Zhang for continuous data to ordered categorical data, when estimates from a pilot study are used in the place of knowledge of the true underlying distribution. A myelin oligodendrocyte glycoprotein-induced experimental autoimmune encephalomyelitis mouse study is used to demonstrate the application of the methods.

Keywords: Ties; Ordinal data; Rank test.

INTRODUCTION

As the non-parametric equivalent of the parametric one-way analysis of variance (ANOVA) model, the rank-based Kruskal–Wallis (1952) test has been widely investigated in statistical science and widely used in pharmaceutical research when the normal residual assumption of its parametric equivalent does not hold. An especially useful scenario of the Kruskal–Wallis test is when the responses are ordinal categorical data, where the normal residual assumption almost never holds. Although the size of the Kruskal–Wallis test has been extensively investigated (see, for example, Iman and Davenport^[1]), the power and sample size calculations have been investigated to a much lesser extent.^[2] The power and sample size procedures proposed by Fan, Zhang, and Zhang^[2] for continuous data can be generated to ordered categorical data, when estimates from a pilot study are used to replace the unknown true underlying distribution. A myelin oligodendrocyte glycoprotein (MOG)-induced experimental autoimmune encephalomyelitis (EAE) mouse study is used to demonstrate the application of the methods.

KRUSKAL–WALLIS TEST FOR ORDERED CATEGORICAL DATA

Let $F_1, \dots, F_K$ denote $K \geq 2$ unknown population cumulative distribution functions, from which K groups of

independent random samples of sizes $N_1, \dots, N_K$ are drawn, respectively. The null and the alternative hypotheses for the Kruskal–Wallis test are

$$\begin{aligned} H_0 : F_1 = \dots = F_K = F^0 \text{ versus} \\ H_a : \text{at least one } F_i \text{ is not equal to } F^0 \end{aligned} \quad (1)$$

Assume an ordered categorical response has C possible values with C being a positive integer. Consider independent random samples $\{X_{ij} \in \{1, \dots, C\} : i = 1, \dots, K, j = 1, \dots, N_i\}$ collected in experiments involving K treatment groups. Let R_{ij} be the rank of the j^{th} observation in the i^{th} sample in the combined sample and $R_i = \sum_{j=1}^{N_i} R_{ij}$. The Kruskal–Wallis test statistic for H_0 versus H_a in Eq. 1 is:

$$S_{\text{KW}} = \frac{\sum_{i=1}^K N_i \left(\frac{R_i}{N_i} - \frac{N+1}{2} \right)^2}{\frac{1}{N-1} \sum_{i=1}^K \sum_{j=1}^{N_i} \left(R_{ij} - \frac{N+1}{2} \right)^2} \quad (2)$$

where $N = \sum_{i=1}^K N_i$ denotes the total sample size.^[3]

Note that when no ties are present, S_{KW} becomes:

$$S_{\text{KW}}^* = \frac{12}{N(N+1)} \sum_{i=1}^K N_i \left(\frac{R_i}{N_i} - \frac{N+1}{2} \right)^2 \quad (3)$$

which is the Kruskal–Wallis test statistic used in the study by Fan, Zhang, and Zhang.^[2]

GENERAL POWER AND SAMPLE SIZE FORMULA

Fan, Zhang, and Zhang^[2] derived the asymptotic properties of S_{KW}^* under the alternative H_a . Theorem 1 below generalizes the asymptotic results to S_{KW} , and its proof can be found in Fan and Zhang.^[4]

THEOREM 1. Under alternative hypotheses H_a in Eq. 1, suppose there exists a distribution F^0 such that $F_i \rightarrow_d F^0$ as $N \rightarrow \infty$ for all $i=1, \dots, K$. Assume $\sigma^2 = \text{Var}\{[F^0(X-) + F^0(X)]/2\} > 0$ with X being a random variable from F^0 . Suppose $\lambda_i = N_i/N \geq \lambda_0$ for all $i \leq K$ and a fixed $\lambda_0 > 0$. Then, as $N \rightarrow \infty$, $(Z_1, \dots, Z_K)^T \rightarrow_d N(O, \sigma^2 \Sigma)$, where $Z_i = N^{-3/2}(R_i - ER_i)$ and $\Sigma = (\lambda_i I\{i=i'\} - \lambda_i \lambda_{i'})_{K \times K}$, for $i, i'=1, \dots, K$. Moreover, the Kruskal-Wallis test statistic S_{KW} approximately has the non-central chi-square distribution $\chi_{K-1}^2(\tau)$, where the non-centrality $\tau = \sum_{i=1}^K N_i \{ER_i/N_i - (N+1)/2\}^2 / (N^2 \sigma^2)$ and a consistent estimate of τ can be obtained by replacing σ^2 with its consistent estimate $s^2/N^2 = \sum_{i=1}^K \sum_{j=1}^{N_i} \{R_{ij} - (N+1)/2\}^2 / (N^2(N-1))$.

Let $p_{ik} = \Pr(X_{ki} < X_{kj}) + \Pr(X_{ki} = X_{kj})/2$ for $i, k=1, \dots, K$. Because $R_i = \sum_{j=1}^{N_i} R_{ij}$, we have $ER_i/N_i - (N+1)/2 = N \sum_{k \neq i} \lambda_k (p_{ik} - 1/2)$ and

$$\tau = \frac{N}{\sigma^2} \sum_{i=1}^K \lambda_i \left\{ \sum_{k \neq i} \lambda_k (p_{ik} - 1/2) \right\}^2 \quad (4)$$

When all p_{ik} s and σ^2 are known, for a study with fixed N and $\lambda_1, \dots, \lambda_K$, we can calculate τ and obtain the power by

$$\text{Power}^{\text{known}} = \Pr\{\chi_{K-1}^2(\tau) > \chi_{K-1, 1-\alpha}^2\} \quad (5)$$

where $\chi_{K-1, 1-\alpha}^2$ is the $(1-\alpha)^{\text{th}}$ quantile of the (central) chi-square distribution with $K-1$ degrees of freedom.

For a study with prespecified power $1-\beta$, the required total sample size for all K groups can be calculated by

$$N^{\text{known}} = \frac{\tau_{\alpha, \beta} \sigma^2}{\sum_{i=1}^K \lambda_i \left\{ \sum_{k \neq i} \lambda_k (p_{ik} - 1/2) \right\}^2} \quad (6)$$

where $\tau_{\alpha, \beta}$ is the solution of the equation $\Pr\{\chi_{K-1}^2(\tau) > \chi_{K-1, 1-\alpha}^2\} = 1-\beta$.

POWER AND SAMPLE SIZE FORMULA FOR ORDERED CATEGORICAL DATA

For the ordinal response data, instead of the knowledge about p_{ik} and σ^2 , practitioners may prespecify the probabilities of observing each category in each group. That is, $\{\pi_{ic} = \Pr(X_{ij} = c) : i=1, \dots, K, c=1, \dots, C\}$ may be known or prespecified. In this case, the power formula 5 and sample size formula 6 need to be reparameterized using $\{\pi_{ic} : i=1, K, c=1, C\}$.

To this aim, we can write that for $i \neq k$,

$$p_{ik} = \sum_{l=1}^{C-1} \sum_{j=l+1}^C \pi_{ij} \pi_{kl} + \frac{1}{2} \sum_{l=1}^C \pi_{il} \pi_{kl} \quad (7)$$

And for σ^2 , we denote $\pi_c = \Pr(X=c) = \sum_{i=1}^K \lambda_i \pi_{ic}$ for $c=1, \dots, C$ with random variable X coming from $F^0 = \sum_{i=1}^K F_i/K$. Then $F^0(c) = \sum_{j=1}^c \pi_j$ and

$$\begin{aligned} \sigma^2 &= \text{Var}\left\{ \frac{F^0(X-) + F^0(X)}{2} \right\} \\ &= E\left\{ \frac{F^0(X-) + F^0(X)}{2} \right\}^2 - \left[E\left\{ \frac{F^0(X-) + F^0(X)}{2} \right\} \right]^2 \\ &= \sum_{c=1}^C \pi_c \left\{ \frac{F^0(c-) + F^0(c)}{2} \right\}^2 - \left[\sum_{c=1}^C \pi_c \left\{ \frac{F^0(c-) + F^0(c)}{2} \right\} \right]^2 \\ &= \sum_{c=1}^C \pi_c \left(\sum_{j=1}^{c-1} \pi_j + \frac{1}{2} \pi_c \right)^2 - \left[\sum_{c=1}^C \pi_c \left(\sum_{j=1}^{c-1} \pi_j + \frac{1}{2} \pi_c \right) \right]^2 \end{aligned} \quad (8)$$

Power for the Kruskal-Wallis test can be calculated by applying Eqs. 7 and 8 in Eq. 5. Required sample size by the Kruskal-Wallis test can be calculated by applying Eqs. 7 and 8 in Eq. 6.

When true values of the parameters $\{\pi_{ic} : i=1, \dots, K, c=1, \dots, C\}$ are unknown and the aim is to calculate power and sample size based on a study with observations $\{X_{ij} \in \{1, \dots, C\} : i=1, \dots, K, j=1, \dots, N_i\}$, the power and sample size can be calculated by replacing p_{ik} s and σ^2 by their corresponding estimates in Eqs. 5 and 6, respectively.

For $i, k=1, \dots, K, i \neq k$, we can estimate p_{ik} by:

$$\hat{p}_{ik} = \frac{1}{N_i N_k} \sum_{j=1}^{N_i} \sum_{l=1}^{N_k} \left(I\{X_{ki} < X_{lj}\} + \frac{1}{2} I\{X_{ki} = X_{lj}\} \right) \quad (9)$$

and estimate σ^2 by $\hat{\sigma}^2 = s^2/N^2$ defined in theorem 1. The power and sample size by this method are denoted as $\widehat{\text{power}}^{\text{known}}$ and $\hat{N}^{\text{known}}$, respectively.

Asymptotically, $\hat{\tau}$ converges to its true value τ . However, with finite sample size in the pilot study, $\hat{\tau}$ is a biased estimator of τ . In our proposed method, we apply adjustments to $\hat{\tau}$ to correct such bias. To guarantee the corrected $\hat{\tau}, \hat{\tau}^*$, to be positive, we may assume that $\hat{\tau}^* = \gamma \hat{\tau}$ for some positive scalar γ . Because $\hat{\tau}$ appears in the denominator of the sample size formula 6, we match the median of $\hat{\tau}^*$ to be τ . By setting median($\hat{\tau}^*$) = median($\gamma \hat{\tau}$) = τ , we have $\gamma = \tau / \text{median}(\hat{\tau})$. Since $\hat{\tau} \rightarrow_d \chi_{K-1}^2(\tau)$, median($\hat{\tau}$) can be estimated by median($\{\chi_{K-1}^2(\hat{\tau})\}$). Therefore,

$$\hat{\tau}^* \approx \hat{\gamma} \hat{\tau} = \frac{\hat{\tau}}{\text{median}\{\chi_{K-1}^2(\hat{\tau})\}} \hat{\tau} \quad (10)$$

With such adjustment, the power Eq. 5 becomes:

$$\widehat{\text{Power}}^{\text{propose}} = \Pr\left\{\chi_{K-1}^2(\hat{\tau}^*) > \chi_{K-1,1-\alpha}^2\right\} \quad (11)$$

and the sample size:

$$\hat{N}_{\text{propose}} = \frac{N\tau_{\alpha,\beta}}{\hat{\tau}} = \hat{N}_{\text{known}} \frac{\text{median}\{\chi_{K-1}^2(\hat{\tau})\}}{\hat{\tau}} \quad (12)$$

Numerical results in Fan and Zhang^[4] show that $\widehat{\text{power}}^{\text{propose}}$ and $\hat{N}_{\text{propose}}$ can give appropriate estimated power and sample size, while $\widehat{\text{power}}^{\text{known}}$ and $\hat{N}_{\text{known}}$ are associated with biased results.

AN EXAMPLE OF AN MOG-INDUCED EAE MOUSE STUDY

The MOG-induced murine EAE is a widely accepted animal model for studying the clinical and pathological features of multiple sclerosis, which is an inflammatory demyelinating disease of the central nervous system.^[5,6] A major indication of EAE in the MOG-EAE model is the spinal cord inflammation. A mouse study was carried out to investigate the effect of a compound C in an MOG-EAE model. This study had four treatment groups—vehicle control (Veh, 20 mice), compound C with concentration 3 mg/kg (C03, 20 mice), compound C with 10 mg/kg (C10, 21 mice), and compound C with 30 mg/kg (C30, 21 mice). All 82 mice were dosed daily after active induction of EAE. At the late phase of disease (day 28), all mice were anesthetized and spinal cords were carefully removed. The lumbar spinal cord of each mouse was dissected, and the histological score for inflammation was determined as in the range from 0 (no inflammation) to 4 (inflammation cells spread out and massive). The goal of the analysis is to compare the treatment effects in terms of the inflammation scores, and in the case when such treatment effects are insignificant (significance level $\alpha = 0.05$), to find the minimum required sample size to achieve desired power in detecting the difference with significance level α . The data can be expressed in terms of the number of mice falling into each score category for each treatment, as in Table 1.

Table 1 MOG-EAE mouse model: Frequencies of mice in each score category for each treatment

Treatment	Score					Total
	0	1	2	3	4	
Veh	2	4	7	7	0	20
C03	5	6	8	1	0	20
C10	2	7	9	1	2	21
C30	7	6	5	2	1	21

Table 2 MOG-EAE mouse model: Power for current study and required sample sizes for future studies to achieve higher powers

N	Current study		Future study		
	$\widehat{\text{power}}^{\text{known}}$	$\widehat{\text{power}}^{\text{propose}}$	Target power	$(\hat{N}_{\text{known}})$	$(\hat{N}_{\text{propose}})$
82	0.599	0.483	0.70	101	130
			0.80	125	161
			0.90	163	210

For this score data, instead of the parametric one-way ANOVA model whose normality assumption is not satisfied, the Kruskal–Wallis test is an appropriate method. The p value for the treatment effects by the Kruskal–Wallis test is 0.0677. One potential reason for such insignificance is that the power of the current study is too low. Since the true values of probabilities π_{ic} s are unknown, we use the $\widehat{\text{power}}^{\text{known}}$ and $\widehat{\text{power}}^{\text{propose}}$ to calculate the power. The results are shown in Table 2. Because the observed treatment effect is insignificant, it is of interest to find the minimum required sample size to detect a difference under significance level α and desired power. Table 2 also shows the required sample sizes for target power 0.70, 0.80, and 0.90, respectively, using the two sample size calculation methods $\hat{N}_{\text{known}}$ and $\hat{N}_{\text{propose}}$. The sample size calculations here assume that the future larger scale study has the same sample size proportions as the current study, i.e., $\lambda_1 : \lambda_2 : \lambda_3 : \lambda_4 = 20 : 20 : 21 : 21$.

In this example, with estimated probabilities π'_{ic} s in the current study, formula 5 ($\widehat{\text{power}}^{\text{known}}$) gives a higher power estimate than the proposed adjusted method (formula 11, $\widehat{\text{power}}^{\text{propose}}$). And the appropriate proposed method shows that the power of the current study is as low as 0.483. In terms of the required sample size to achieve power 0.8, the proposed method ($\hat{N}_{\text{propose}}$) suggests a total sample size 161, which is about double the current sample size. But formula 6 ($\hat{N}_{\text{known}}$) gives a much smaller sample size of 125.

SAS® code to realize the power and sample size formulas is available upon request from Dr. C. Fan.

CONCLUSIONS AND DISCUSSIONS

Under H_a , when the true probability mass functions of $F_1, \dots, F_K$ are known, the power and sample size calculation methods, formulas 5 and 6, can be applied. When the probability mass functions are unknown but their estimates can be obtained from a pilot study, the proposed power and sample size calculation methods, formulas 11 and 12, are appropriate.

For the proposed power calculation to be accurate, the sample size in each group in the pilot study should not be too small. The power formulas do not work well with

sample size 60 or 100. The proposed sample size calculation may not be accurate when the power of the pilot study is too small.

In practice, the true values of π_{ic} s are seldom known. Therefore, practitioners may estimate the probability mass functions π_{ic} s from a historical study and use the estimated π_{ic} s to plan future studies by calculating the required sample sizes with Monte Carlo simulations. However, this does not take the variation in $\hat{\pi}_{ic}$ into consideration. Although this is not an issue in the two-sample Wilcoxon test,^{[2][7]} for the K-sample Kruskal–Wallis test with $K \geq 3$, this causes overestimation of the power and underestimation of the required sample size. Since the Monte Carlo power and sample size calculation methods can be used only with true values of π_{ic} s, it is important to have confidence in the source of π_{ic} s when using the methods.

Kullback–Leibler Divergence for Evaluating Equivalence

Vladimir Dragalin

GlaxoSmithKline, Collegeville, Pennsylvania, U.S.A.

Abstract

Kullback–Leibler Divergence for Evaluating Equivalence The Kullback–Leibler divergence metric is a viable alternative to that proposed by the FDA for the assessment of bioequivalence. This entry details the benefits of this type of bioequivalence study by providing models for use.

INTRODUCTION

In many applications, we are interested in showing that two independent samples arise from similar underlying populations with distribution functions F and G , respectively. Testing the hypothesis $H_0: F = G$ vs. the alternative $H_a: F \neq G$ is not suitable for the assessment of similarity of populations. Even when the observed p value of a test for H_0 is large, this does not allow for a controlled error rate when assessing similarity. In equivalence trials, the issue is not to show a difference between the two populations, but to demonstrate that one population is not different from the other by more than a prespecified irrelevant amount. The assessment of equivalence is of interest in various fields: psychology,^[1] chemistry,^[2] environmental statistics,^[3] bridging assessment studies,^[4] vaccine consistency,^[5] neurophysiology,^[6] to name a few. Bioequivalence testing has become a challenging field during the last two decades with an increased interest from academia, regulatory agencies, and pharmaceutical industry.^[7]

Bioequivalence trials seek to demonstrate the similarity of the new formulation, such as a new generic product, to the old formulation, such as the innovator's product, based on the surrogate outcome of plasma concentration of the drug and/or its metabolites. A new formulation that demonstrates a much greater or much lower bioavailability is unacceptable.

The area under the concentration curve (AUC), the maximum concentration ($C_{\max}$), and the time to maximum concentration ($T_{\max}$) are commonly used pharmacokinetic characteristics of the tested formulations.

OVERVIEW

In general, bioequivalence represents a statement about distance between distributions of the pharmacokinetic responses on test and reference formulations. Recently, Dragalin et al.^[8] proposed a unified methodology, based on the Kullback–Leibler divergence (KLD) for the assessment

of bioequivalence that encompasses all three aspects: average bioavailability, prescribability, and switchability. To demonstrate bioequivalence, the following hypotheses are tested:

$$H_0: d(f_T, f_R) > d_0 \text{ vs. } H_a: d(f_T, f_R) \leq d_0$$

where f_T and f_R are the appropriate density functions of the observations from test and reference formulation, respectively, $d(f_T, f_R)$ is KLD, and d_0 is the goalpost to be set by a regulator.

If we reject the null hypothesis H_0 on the basis of observations from a trial, then we may conclude that the test and reference formulations are bioequivalent. On the other hand, if we do not reject H_0 , then bioequivalence is not proved. This does not necessarily mean that the two formulations are not bioequivalent; perhaps, more observations are needed to prove it. Equivalently, we may construct a one-sided confidence interval with upper bound d_U for $d(f_T, f_R)$ and check it with d_0 ; if $d_U < d_0$, then accept bioequivalence; otherwise, reject it.

The current worldwide regulatory standard for evaluating bioequivalence is the so-called average bioequivalence (ABE), which compares the means μ_T and μ_R of the distributions of the response variable on the two formulations, test (T) and reference (R), respectively. The ABE criterion is formulated as:^[9]

$$(\mu_T - \mu_R)^2 \leq \vartheta_A$$

where ϑ_A is a goalpost, a standard set by regulatory agencies that defines how “close” the two formulations must be to be declared bioequivalent. Various statistical methods for evaluating the ABE have appeared.^[10–14] The so-called two one-sided tests^[15,16] are now considered to be the standard method.

However, many authors^[17–20] argue that in some situations, it is not sufficient to focus only on population averages of test and reference formulations. Besides means, the variances σ_T^2 and σ_R^2 of the test and reference distributions,

respectively, could be used to evaluate the bioequivalence. Population bioequivalence (PBE) was introduced to evaluate the prescribability aspect of bioequivalence testing and is meaningful in the clinical setting where the two formulations are equally prescribable to a new patient. The PBE criterion is formulated as:^[21,22]

$$\frac{(\mu_T - \mu_R)^2 + \sigma_T^2 - \sigma_R^2}{\sigma_{\max}^2} \leq \vartheta_p \quad (1)$$

where $\sigma_{\max}^2 = \max\{\sigma_0^2, \sigma_R^2\}$ and ϑ_p and σ_0^2 are goalposts.

However, the equality of bioavailability distributions does not imply that the responses to the two formulations within the same individual patient will be sufficiently close. Individual bioequivalence (IBE) of two formulations means that a patient currently on the reference formulation can be switched to the new test formulation with assurance that the new drug will yield comparable safety and efficacy to that of the product for which it is being substituted. The following mixed-scaling criterion is recommended:^[21,22]

$$\frac{(\mu_T - \mu_R)^2 + \sigma_D^2 + \sigma_{WT}^2 - \sigma_{WR}^2}{\sigma_{W\max}^2} \leq \vartheta_i \quad (2)$$

where σ_{WT}^2 and σ_{WR}^2 are within-subject variances for the T and R formulations, respectively, σ_D^2 is the subject-by-formulation interaction variance component, $\sigma_{W\max}^2 = \max\{\sigma_{W0}^2, \sigma_{WR}^2\}$ and ϑ_i and σ_{W0}^2 are goalposts. Because the within-subject variance of each treatment cannot be separately estimated in a two-period, two-sequence crossover design with sequences {TR, RT}, a design in which subjects obtain repeats of T or R are needed. An example of such a *replicate* design is the one with sequences {TRTR, RTRT}; for others, see Ref. [23].

In addition to the comparison of means, both the PBE and IBE criteria compare variances between the test and reference formulations. While the PBE criterion focuses on total variances, the IBE criterion considers within-subject variability and subject-by-formulation interaction.

The general idea by Dragalin et al.^[8] is to use the KLD as a measure of discrepancy between the distributions of the test and reference formulations. The model for the response on T and R is a standard, linear mixed-effects model. The KLD permits a natural hierarchy of variation, allowing bioequivalence to be considered at various levels: within-subject, between-subject, and overall. There is a KLD for each level. Two formulations are declared bioequivalent if the upper bound of $(1 - \alpha)100\%$ confidence interval for the KLD is less than a given goalpost.

This new approach allows a much more elegant treatment of bioequivalence evaluation than the current ad hoc approaches. It overcomes many of the weaknesses of the conventional methods based on Eqs. 1 and 2 and addresses the conceptual issues with current criteria. In particular, the KLD 1) possesses the natural hierarchical property

that $IBE \Rightarrow PBE \Rightarrow ABE$; 2) satisfies the properties of a true distance; 3) is invariant to monotonic transformations of the data; 4) easily generalizes to the multivariate case where equivalence on more than one parameter (e.g., AUC, $C_{\max}$, and $T_{\max}$) is required; and 5) is applicable over a wide range of distributions of the response variable (e.g., those in the exponential family).

In the next section, the general setting is introduced based on a linear mixed model for the pharmacokinetic responses. The KLD criteria for PBE and IBE are presented. The merits of the KLD approach are provided and desirable features are given relative to improving the drawbacks suffered by the conventional criteria. The “Individual Bioequivalence” section focuses on IBE where a measure is proposed based on the KLD between the distributions of the two formulations, but this time at the individual level.

DESIRABLE FEATURES OF BIOEQUIVALENCE CRITERIA AND CONCEPTUAL ISSUES WITH CURRENT ONES

In bioequivalence studies, the following model for observations is commonly accepted. Let X_{ijk} be the k th response ($k = 1, 2, \dots$) for the j th subject on treatment formulation t ($t = T, R$) and

$$X_{ijk} = \mu_t + v_{ij} + \varepsilon_{ijk} \quad (3)$$

where v_{ij} is the (random) mean deviation from the population average μ_t of the t th formulation for the j th subject and ε_{ijk} is the (random) within-subject deviation from the individual subject's response on repeated administrations of the t th formulation. Conditional on the j th subject, v_{ij} and ε_{ijk} are independent with mean zero and variances $\text{Var}(v_{ij}) = \sigma_{Bt}^2$ (the between-subject variance) and $\text{Var}(\varepsilon_{ijk}) = \sigma_{Wt}^2$ (the within-subject variance). In addition, we assume $\text{Cov}(\varepsilon_{ijk}, \varepsilon_{ijk'}) = 0$ for $k \neq k'$. For the j th subject, v_{Tj} and v_{Rj} are correlated with correlation coefficient ρ and the subject-by-formulation interaction variance

$$\sigma_D^2 = \text{Var}(v_{Tj} - v_{Rj}) = \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho\sigma_{BT}\sigma_{BR}$$

The current Food and Drug Administration (FDA)-proposed criteria for the evaluation of ABE, PBE, and IBE are functions of the means, within-subject, and between-subject variances, and the subject-by-formulation interaction. In essence, each of these criteria is an ad hoc attempt to assess the discrepancy between distributions of the pharmacokinetic responses on test and reference formulations. However, different measures of such discrepancy are used for different types of bioequivalence: ABE is evaluated in terms of the difference in means of T and R; PBE is evaluated in terms of the second moment of the between-subject differences in bioavailability of the T and R formulations with that of R vs. R itself; while the

IBE is evaluated in terms of the second moment of the within-subject differences.

Assume that the response variables are distributed according to normal distributions with means μ_T and μ_R and variances σ_T^2 and σ_R^2 on test and reference formulations, respectively. In this case, the KLD is

$$d(f_T, f_R) = \frac{1}{2} \left\{ (\mu_T - \mu_R)^2 + \sigma_T^2 + \sigma_R^2 \right\} \times \left(\frac{1}{\sigma_T^2} + \frac{1}{\sigma_R^2} \right) - 2 \quad (4)$$

Particularly, in case of model (3), $\sigma_T^2 = \sigma_{BT}^2 + \sigma_{WT}^2$ and $\sigma_R^2 = \sigma_{BR}^2 + \sigma_{WR}^2$.

Under the assumption that the two formulations have the same variance, i.e., $\sigma_T^2 = \sigma_R^2 = \sigma^2$, the KLD becomes

$$d(f_T, f_R) = \frac{(\mu_T - \mu_R)^2}{\sigma^2} \quad (5)$$

which differs from the current (unscaled) ABE measure $(\mu_T - \mu_R)^2$.^[21,22]

We now consider various aspects of the FDA-proposed measures of bioequivalence and indicate advantages possessed by the KLD measure.

Desirable Properties for Distance

Let F and G be two distributions with densities f and g , respectively. The distance (discrepancy, divergence) between f and g is denoted by $\Delta(f, g)$. A true distance should satisfy

1. $\Delta(f, g) \geq 0$ and $\Delta(f, g) = 0$ iff $f = g$
2. $\Delta(f, g) \leq \Delta(f, q) + \Delta(q, g)$ (triangle inequality)
3. $\Delta(f, g) = \Delta(g, f)$ (symmetry)

where q is a third arbitrary density.

Kullback and Leibler^[24] introduced a measure of the “directed divergence” between statistical populations,

$$I(f, g) = E_f \log \frac{f(X)}{g(X)}$$

variously known as Kullback–Leibler information, information for discrimination, I divergence, the error, or the directed divergence. However, $I(f, g)$ is not symmetric; also, it does not satisfy the triangle inequality in general. Jeffreys^[25] considered the symmetric divergence or J divergence:

$$\Delta_1(f, g) = [I(f, g) + I(g, f)]^{1/2} = \left[\int (f(x) - g(x))(\log f(x) - \log g(x)) dx \right]^{1/2}$$

In the normal distributions case, $\Delta_1(f, g)$ satisfies all three distance properties when $E_f(X) = E_g(X)$ or $\text{Var}_f(X) = \text{Var}_g(X)$. Thus $\Delta_1(f, g)$ can be considered as a distance between distributions. However, it is more convenient to work with $d(f, g) = \Delta_1^2(f, g)$ and, although abusing the terminology, we will call the function $d(f, g)$ the Kullback–Leibler divergence.

It is clear from the definition of the KLD that $d(f, g) \geq 0$ with equality if and only if $f(x) = g(x)$ for all x . It is symmetric and convex in the pair (f, g) .

The present approach in bioequivalence trials^[21,22] is to use the following discrepancy measures:

$$\begin{aligned} \text{ABE} : \delta &= (\mu_T - \mu_R)^2 \\ \text{PBE} : \bar{d} &= \frac{(\mu_T - \mu_R)^2 + \sigma_T^2 - \sigma_R^2}{\sigma_R^2} \end{aligned}$$

The discrepancy measure $\bar{d}$ of the PBE criterion violates all three properties of a true distance: $\bar{d} = 0$ not only when $\mu_T = \mu_R$ and $\sigma_T^2 = \sigma_R^2$, but also for a test formulation with a different mean ($\delta > 0$) and $\sigma_T^2 = \sigma_R^2 - \delta$. Notice that δ might be big enough (thus the lack of average bioequivalence is quite evident), but with a small σ_T^2 (relative to σ_R^2), the test formulation can be declared equal to the reference formulation. Moreover, for reference formulations with relatively large variability σ_R^2 , the “distance” $\bar{d}$ between test and reference formulation might even be negative! Furthermore, PBE does not always imply ABE. The criterion for ABE, $(\mu_T - \mu_R)^2 \leq \theta_A$, requires different values for the “regulatory” bound θ_A for formulations with “small,” “moderate,” and “large” variability. On the other hand, the KLD bioequivalence measure $d(f_T, f_R)$ is in standardized units, and both ABE and PBE criteria are unified as

$$d(f_T, f_R) < d_0$$

Scaling and Symmetry

The current criteria for PBE and IBE provide goalposts dependent on variability of the reference formulation and allow scaling for both highly variable and narrow therapeutic range drugs, and reward for reduced variability in the test formulation. However, the scaling mainly corresponds to a modification of the bioequivalence acceptance limits and ought to be an issue independent of IBE, PBE, and ABE. The proposed by FDA mixed-scaling approach (with $\sigma_{\max}^2$ or $\sigma_{W\max}^2$) has a discontinuity at the change points (σ_0^2 or σ_{W0}^2) from constant to reference scaling; for example, if the estimate of σ_R^2 is just above σ_0^2 , the confidence interval will be wider than just below σ_0^2 .

Moreover, the scaling in both the PBE and IBE criteria is asymmetric with respect to T and R. One may argue that in bioequivalence studies, the reference and test formulation cannot be equally treated: It should be shown that the

test is equivalent to the reference, and not the other way around. However, for physicians and patients, bioequivalent drug formulations should be interchangeably used to achieve a similar therapeutic effect. Bioequivalence studies in fact serve as surrogates for clinical trials in evaluation of therapeutic equivalence in efficacy and safety between the innovator product and its generic copies. A new formulation that demonstrates much greater or much lower bioavailability is unacceptable. Furthermore, the bioequivalence evaluation of the two generic formulations may also be of interest. Therefore, in this sense, both formulations should be symmetrically treated. These issues are resolved by the new method based on the KLD.

Interpretation on the Original Scale

The current bioequivalence criteria are usually formulated on the logarithmic scale of the pharmacokinetic characteristic. The ABE for the population means μ_T and μ_R on the logarithmic scale [e.g., $\ln(\text{AUC})$ being normal] can be expressed as the ratio of the population medians on the original scale. However, the aggregate criteria for PBE and IBE on the logarithmic scale have no obvious translation into the natural parameter space. On the other hand, the KLD is invariant to a continuously differentiable monotonic transformation.^[8] This implies that if a bioequivalence property (ABE, PBE, or IBE) defined in terms of the KLD holds for a given data set, then the property remains valid for any monotone transformation of the data.

Design Requirements

An increased burden for the pharmaceutical industry may arise with use of the FDA individual bioequivalence criterion in that fully or partially replicated designs with at least three periods are required and should be performed in study subjects from the general population. Moreover, existing publications do not clearly indicate that the issue of switchability is properly addressed by the proposed IBE criterion.^[26] The KLD approach has the additional advantage of being able to use data from conventional two-way crossover designs (see details in “Design-Driven Individual Bioequivalence Criteria”).

Logical Hierarchy of Conclusions

Another important issue is the desired logical hierarchy of bioequivalence conclusions: IBE should imply PBE, which in turn should imply ABE. Unfortunately, current FDA approaches do not ensure this kind of hierarchy. Two formulations might satisfy the FDA IBE criterion, but fail to be declared PBE. Or, two formulations might satisfy the PBE criterion, i.e., have both similar means and variances, yet cannot be declared bioequivalent based on a comparison of means alone. On the other hand, the KLD-based criteria for ABE, PBE, and IBE possess this desirable property of

logical hierarchy of conclusions: $\text{IBE} \Rightarrow \text{PBE} \Rightarrow \text{ABE}$. (See details in “Individual Bioequivalence.”)

Generalization to Exponential Family of Distributions

The KLD approach may be used for any type (not only normal) of distributions. A similar formula for $d(f_T, f_R)$ can be derived for the general exponential family of distributions (in canonical form):

$$f_\theta(x) = \exp \left\{ \sum_{i=1}^k \theta_i T_i(x) - \psi(\theta) \right\} h(x)$$

where $\theta = (\theta_1, \theta_2, \dots, \theta_k)$ is a k -dimensional parameter, ψ is a real-valued function of the parameters, and T_i are real-valued statistics. Using

$$E_\theta(T_i(X)) = \frac{\partial \psi(\theta)}{\partial \theta_i}$$

straightforward calculations yield

$$d(f_{\theta_T}, f_{\theta_R}) = \sum_{i=1}^k (\theta_{Ti} - \theta_{Ri}) \times \left[\frac{\partial \psi(\theta)}{\partial \theta_i} \Big|_{\theta=\theta_T} - \frac{\partial \psi(\theta)}{\partial \theta_i} \Big|_{\theta=\theta_R} \right]$$

Particular cases are:

- Kullback–Leibler divergence for two exponential distributions: $(\lambda_T - \lambda_R)((1/\lambda_R) - (1/\lambda_T))$.
- Kullback–Leibler divergence for two Bernoulli distributions: $(p_T - p_R) \log((p_T(1 - p_R))/((1 - p_T)p_R))$. [Notice the difference from other discrepancy measures for Bernoulli case such as difference in proportions $(p_T - p_R)$, risk ratio p_T/p_R , and odds ratio $(p_T(1 - p_R)/(1 - p_T)p_R)$.
- Kullback–Leibler divergence for two Poisson distributions: $(\lambda_T - \lambda_R) \log(\lambda_T/\lambda_R)$.

Generalization to Multivariate Case

In most bioequivalence studies (exceptions are Refs. [13,27–29]), different characteristics of the pharmacokinetics and pharmacodynamics, such as AUC, $C_{\max}$, $T_{\max}$, etc. are separately analyzed.

The approach based on the KLD can be easily extended to the multivariate situation when all these characteristics are simultaneously analyzed. Let $\mathbf{X}_{Rj}$ and $\mathbf{X}_{Tj}$ be observations from the reference and test formulations, but this time they are random vectors (of dimension $p \geq 2$) with components corresponding to various characteristics. Again, let f_R and f_T be the corresponding density functions. Then, it

can be verified that under the assumption that f_R and f_T are multivariate normal density functions with mean vectors μ_R and μ_T and positive definite covariance matrices Σ_R and Σ_T , respectively:

$$\begin{aligned} d(f_T, f_R) &= \frac{1}{2} \left\{ (\mu_T - \mu_R)^T (\Sigma_T^{-1} + \Sigma_R^{-1}) (\mu_T - \mu_R) \right. \\ &\quad \left. + \text{tr}(\Sigma_T^{-1} \Sigma_R + \Sigma_T \Sigma_R^{-1}) - 2p \right\} \\ &= \frac{1}{2} \text{tr} \left\{ [(\mu_T - \mu_R)(\mu_T - \mu_R)^T + \Sigma_T + \Sigma_R] \right. \\ &\quad \left. \times [\Sigma_T^{-1} + \Sigma_R^{-1}] \right\} - 2p \end{aligned}$$

where the superscript T to a vector means “transposed” and -1 to a matrix means it is inverse, tr means the trace of a matrix. Note the similarity with the definition of the KLD for PBE in the univariate case.

INDIVIDUAL BIOEQUIVALENCE

If, besides average bioavailability and prescribability, one is also interested in switchability of the test and reference formulations, an individual bioequivalence measure may be proposed that is also based on the KLD, but this time at the individual level.

Suppose that for each subject in the trial, a pair (X_{Rj}, X_{Tj}) of observations is available. Assuming that

$$\begin{aligned} X_{Rj} | v_{Rj} &\sim \mathbf{N}(\mu_R + v_{Rj}, \sigma_{WR}^2) \quad \text{and} \\ X_{Tj} | v_{Tj} &\sim \mathbf{N}(\mu_T + v_{Tj}, \sigma_{WT}^2) \end{aligned}$$

where $\mathbf{N}(\mu, \sigma^2)$ is normal distribution with mean μ and variance σ^2 , we can calculate as in Eq. 4 the conditional KLD between the distributions of X_{Rj} and X_{Tj} , conditioned on the j th subject-related characteristics (v_{Rj}, v_{Tj}) :

$$\begin{aligned} d(f_{T,v}, f_{R,v}) &= \frac{1}{2} \left\{ (\mu_T + v_{Tj} - \mu_R - v_{Rj})^2 + \sigma_{WT}^2 \right. \\ &\quad \left. + \sigma_{WR}^2 \right\} \left(\frac{1}{\sigma_{WT}^2} + \frac{1}{\sigma_{WR}^2} \right) - 2 \end{aligned}$$

Additionally, assuming that (v_{Rj}, v_{Tj}) has a bivariate normal distribution with zero means, we can calculate the unconditional KLD integrating out the effect of (v_{Rj}, v_{Tj}) :

$$\begin{aligned} d(f_T, f_R) &= \frac{1}{2} \left\{ (\mu_T - \mu_R)^2 + \sigma_D^2 \right. \\ &\quad \left. + \sigma_{WT}^2 + \sigma_{WR}^2 \right\} \times \left(\frac{1}{\sigma_{WT}^2} + \frac{1}{\sigma_{WR}^2} \right) - 2 \end{aligned} \quad (6)$$

where $\sigma_D^2 = \text{Var}(v_{Tj} - v_{Rj}) = \sigma_{BT}^2 + \sigma_{BR}^2 - 2\rho\sigma_{BT}\sigma_{BR}$.

We call this the KLD for IBE. Notice that this measure is based on the same parameters as the currently proposed

FDA measure (Eq. 2). However, the KLD for IBE fulfils the desired distance properties 1 and 3, while Eq. 2 fails on all three properties of a true distance.

There is a desired logical hierarchy of bioequivalence conclusions in the KLD setting: $\text{IBE} \Rightarrow \text{PBE} \Rightarrow \text{ABE}$. [Notice that this is not the case with the current criteria for PBE (Eq. 1) and IBE (Eq. 2).] Indeed, let $f_{R,v}(x)$ be the density function for X_{Rj} conditional on the subject-formulation effects (v_{Rj}, v_{Tj}) and similarly $f_{T,v}(x)$ be the conditional density function for X_{Tj} . Also, let $\varphi(v_R, v_T)$ be the joint density of the subject-formulation effects on the same subject. Then, the KLD for IBE can be defined as

$$d(f_T, f_R) = E_\varphi \left[E_{f_{R,v}} \log \frac{f_{R,v}}{f_{T,v}} + E_{f_{T,v}} \log \frac{f_{T,v}}{f_{R,v}} \right]$$

Because of the convexity in the pair (f_T, f_R) of $d(f_T, f_R)$, we have

$$\begin{aligned} d_I(f_T, f_R) &= E_\varphi \left[E_{f_{R,v}} \log \frac{f_{R,v}}{f_{T,v}} + E_{f_{T,v}} \log \frac{f_{T,v}}{f_{R,v}} \right] \\ &\geq E_{f_R} \log \frac{f_R}{f_T} + E_{f_T} \log \frac{f_T}{f_R} = d_P(f_T, f_R) \end{aligned}$$

where $f_i(x) = \int f_{i,v}(x) \varphi(v_R, v_T) dv_R dv_T$. Here we have used indices I and P to distinguish between KLDs for individual (Eq. 6) and population (Eq. 4) bioequivalence. Similarly, we can show the implication $\text{PBE} \Rightarrow \text{ABE}$ from Eqs. 4 and 5.

Therefore IBE is a stronger property than PBE, which in turn is a stronger property than ABE, and the KLD methodology offers the following testing of a priori ordered hypotheses in a stepwise manner for bioequivalence evaluation:

First: Average bioequivalence using criterion based on Eq. 5.
If shown: Population bioequivalence based on Eq. 4.
If also shown: Individual bioequivalence based on Eq. 6.

The generalization of KLD for IBE to the multivariate case is straightforward:

$$\begin{aligned} d(f_T, f_R) &= \frac{1}{2} \text{tr} \left\{ [(\mu_T - \mu_R)(\mu_T - \mu_R)^T + \Sigma_D \right. \\ &\quad \left. + \Sigma_{WT} + \Sigma_{WR}] [\Sigma_{WT}^{-1} + \Sigma_{WR}^{-1}] \right\} - 2p \end{aligned}$$

where Σ_{WR} and Σ_{WT} are covariance matrices for the error vectors ε_R and ε_T , respectively, and $\Sigma_D = \text{Cov}(v_T - v_R)$.

Design-Driven Individual Bioequivalence Criteria

For IBE evaluation using the IBE measure (Eq. 6), one needs at least a three-period crossover design as in the case

of current criteria (Eq. 2).^[20] However, the switchability criterion can also be formulated as follows:

the test formulation T is switchable with the reference R if the KLD between the bivariate distribution of (X_{Rj1}, X_{Tj2}) and the bivariate distribution of (X_{Rj1}, X_{Rj2}) is less than some goalpost d_i .

Under the assumptions that v_{ij} and ε_{ijk} are normally distributed, we obtain the following:

1. (X_{Rj1}, X_{Tj2}) have a bivariate normal distribution with mean $\mu_T = (\mu_R, \mu_T)$ and covariance matrix

$$\Sigma_T = \begin{pmatrix} \sigma_R^2 & \rho_T \sigma_T \sigma_R \\ \rho_T \sigma_T \sigma_R & \sigma_T^2 \end{pmatrix}$$

2. (X_{Rj1}, X_{Rj2}) have a bivariate normal distribution with mean $\mu_R = (\mu_R, \mu_R)$ and covariance matrix

$$\Sigma_R = \begin{pmatrix} \sigma_R^2 & \rho_R \sigma_R^2 \\ \rho_R \sigma_R^2 & \sigma_R^2 \end{pmatrix}$$

where $\sigma_T^2 = \sigma_{BT}^2 + \sigma_{WT}^2$, $\sigma_R^2 = \sigma_{BR}^2 + \sigma_{WR}^2$, $\rho_T \sigma_T \sigma_R / (\sigma_T \sigma_R)$, and $\rho_R = \sigma_{BR}^2 / \sigma_R^2$.

As in the PBE multivariate case, we obtain:

$$d(f_T, f_R) = \frac{1}{2} \left\{ (\mu_T - \mu_R)^T (\Sigma_T^{-1} + \Sigma_R^{-1}) (\mu_T - \mu_R) + \text{tr}(\Sigma_T^{-1} \Sigma_R + \Sigma_T \Sigma_R^{-1}) \right\} - 4 \quad (7)$$

Note that $d(f_T, f_R) = 0$ iff $\mu_T = \mu_R$, $\sigma_T = \sigma_R$, and $\rho_T = \rho_R$. This is another definition of the KLD for IBE driven by both the definition of the switchability and the design used for its assessment. Notice that the two-period, two-sequence, two-formulation design can be used for evaluating individual bioequivalence using the KLD (Eq. 7), while the IBE criteria (Eqs. 2 and 6) require at least three-period replicate designs.^[20]

Any replicate crossover design with at least two realizations within a patient and within a treatment of the forms

1. three-period, two-sequence, two-formulation design {TRT, RTR},
2. four-period, two-sequence, two-formulation design {TRTR, RTRT},

etc. may also be used for this kind of individual bioequivalence trials. Each such design implies a definition of switchability and the respective KLD can be constructed.

To assure drug switchability, it is generally suggested that bioequivalence be assessed within the same individuals. In the simplest case, the observations in such IBE

studies are matched pairs (X_{Tj}, X_{Rj}) . Because the concept of “switchability” actually means “agreement” between the bioavailabilities of the two formulations, the statistical procedures used in agreement problems^[30] are adequate in IBE assessment. The Total Least Square method was proposed in Dragalin and Fedorov^[31] as an alternative methodology for IBE evaluation. The proposed approach is very intuitive and transparent and can be easily extended to allow the parametric comparison of PK curves of the two formulations, not just its parameters. (See also Refs. [32,33].)

OTHER MEASURES OF DISCREPANCY

There are other distances that are functionals of the entire distribution, not only of their first (one or two) moments. The simplest one is the total variation

$$\Delta_2(f, g) = \int_{-\infty}^{\infty} |f(x) - g(x)| dx$$

which is the area between the two density functions. This distance is generalized to the so-called L_p distance. The limiting $p \rightarrow \infty$ case of the L_p distance is the ℓ_1 distance. Czado and Munk^[34,35] considered trimmed Mallow distance for bioequivalence evaluation. In general, for two continuous cdf's, F and G , the trimmed Mallow distance is defined as

$$\Delta_3(F, G; \alpha) = \left\{ \frac{1}{1-2\alpha} \int_{\alpha}^{1-\alpha} |F^{-1}(u) - G^{-1}(u)|^2 du \right\}^{1/2}, \quad \alpha \in [0, 1/2)$$

For the normal case,

$$\Delta_3(F, G; \alpha) = \left\{ \frac{1}{1-2\alpha} \left[(\mu_T - \mu_R)^2 + (\sigma_T - \sigma_R)^2 \times \left(1 - 2 \frac{z_{1-\alpha} \varphi(z_{1-\alpha})}{1-2\alpha} \right) \right] \right\}^{1/2}$$

where $z_{1-\alpha}$ and $\varphi(z_{1-\alpha})$ is the $(1 - \alpha)$ quantile and density, respectively, of the standard normal distribution. The trimming puts slightly more weight on the mean difference than on difference of the scales.

Another well-known discrepancy measure between two distributions is the Hellinger distance:

$$\Delta_4(f, g) = \left\{ \int \left[\sqrt{f(x)} - \sqrt{g(x)} \right]^2 dx \right\}^{1/2}$$

For the normal case,

$$\Delta_4(f, g) = \left\{ 2 \left(1 - \sqrt{\frac{2\sigma}{1+\sigma^2}} \exp \left\{ -\frac{\delta^2}{4(1+\sigma^2)} \right\} \right) \right\}^{1/2}$$

where $\delta = (\mu_T - \mu_R)/\sigma_R$ is the standardized (in standard deviation units of the reference R) difference in means and $\sigma = \sigma_T/\sigma_R$ is the ratio in test and reference intrasubject variability. Notice that the Hellinger distance, as well as the KLD for PBE (Eq. 4), depends only on δ and σ . This means that the goalpost for each of these two discrepancy measures is independent of the variability of the reference drug. In contrast, the goalpost for PBE based on the FDA measure or the trimmed Mallow distance depends on σ_R . Fig. 1 illustrates the contour plots for the four measures for PBE: KLD, FDA, trimmed Mallow, and Hellinger. For fair comparison, the FDA and trimmed Mallow measures are plotted assuming $\sigma_R = 1$. On the x axis it is the standardized difference in means δ , while on y axis it is the ratio in test and reference intrasubject variability σ . One can immediately see the drawbacks of the FDA PBE: An increase of one unit in δ can be offset by a tenfold decrease in intrasubject variability, $\sigma = 0.1$. The other three measures do not allow any mean–variability tradeoff. Also, notice the difference between an aggregate criterion such as KLD and a disaggregate one,^[7] in which standardized difference in means δ and intrasubject variability σ are individually evaluated. In the latter case, the parameter space corresponding to PBE is a rectangle, while in the former it is an ellipse centered at (0,1).

Fig. 1 Contour plots for different discrepancy measures in PBE

SIMULATIONS

Dragalin et al.^[8] present a simulation study for comparing the FDA and KLD metrics in assessing IBE. They consider 16 scenarios for different configurations of the mean difference $\mu_T - \mu_R$, high- and low-variability drugs σ_{WR}^2 , ratio of variances $\sigma_{WT}^2/\sigma_{WR}^2$, and subject-by-formulation interaction σ_D^2 .

The design used in the simulations has 18 subjects on each of the two sequences TRTR and RTRT. The normally distributed data generated in each simulation is based on Eq. 3. Given a particular scenario, the true values of the relevant means and variances were specified and a sample of 144 observations (four observations per subject) was generated.

These simulated data were then used to determine an upper 95% bound for each of the FDA and KLD metrics by bootstrap sampling (2000 bootstrap samples per simulated data set). In each bootstrap sample (performed preserving the number of subjects per sequence^[21]), observations were analyzed using a two-stage (mixed effect, restricted maximum likelihood) linear model including terms for sequence, period, formulation, and period by sequence-within-formulation interaction in the model. Subject within sequence was specified as a random effect, and a heteroscedastic compound symmetric matrix for between-subject variances was assumed in accordance with the original recommendations from the FDA^[21] and from previous research.^[36] Estimates for the parameters of interest were derived and used to estimate the metrics of interest in each bootstrap sample.

The KLD appeared directly sensitive to changes in the means between formulations and the presence of a subject-by-formulation interaction—directly measuring discrepancy between formulations as expected. The FDA metric's behavior appeared insensitive to some factors, consistent with earlier findings,^[36] and conclusions of bioequivalence may be overly dependent on the level of within-subject variation.

To assess how the metrics perform in practice, the AUC and $C_{\max}$ data of 22 data sets from 15 randomized, replicate-design studies were also analyzed. Descriptions of the data sets and estimates derived using the two-stage mixed effect model are given in Ref. [36].

The KLD metric appeared to be a more stringent criterion (i.e., harder to demonstrate IBE) than the FDA metric. The FDA metric by chance finds a slight increase in within-subject test variance unacceptable in the coincident presence of a small subject-by-formulation interaction and in the presence of changes in means between formulations. The KLD assesses these slight changes relative to the overall background noise (as measured by the within-subject variances for test and reference formulations).

The KLD metric rejected IBE for a greater number of data sets than the FDA metric. The problems with inference (observed mean/variance tradeoffs) previously identified for the FDA metric did not appear as prevalent with inference using the KLD, and overall, inference using the KLD appeared more consistent with a procedure that would be expected to be an extension of average bioequivalence.

The FDA Guidance (2001)^[22] recommends the modified large sample (MLS) confidence intervals^[37] for assessment of PBE and IBE. The method proposed in Ref. [37] requires independence of estimators of variance components present in the linear combination defining the FDA PBE and IBE measures. However, under crossover designs usually used in bioequivalence evaluation, the estimators of these variance components are dependent. Using a chi-square representation of a quadratic form of a multivariate normal vector, Lee et al.^[38] extend the MLS method to the situation where estimators of variance components are dependent. It will be interesting to use this new methodology in comparing the KLD with other metrics.

CONCLUSION

The KLD metric is a viable alternative to that proposed by the FDA for the assessment of bioequivalence. It appears to be sensitive to changes in mean response between formulations and to the detection of subject-by-formulation interaction. Identification of differences between individual responses to formulation are clearly identified in low-variability drug products, and bigger quantitative differences must be observed before the KLD flags them as being important for high-variability products.

Formulations are not “rewarded” for being less variable when using the KLD metric while they frequently are when using the FDA metric.^[36] Thus coincident differences in average bioavailability with decreased variance for the test formulation may allow market access under the proposed FDA metric,^[26] and this does happen in practice.^[36] Use of the KLD metric, which does not allow for such a “tradeoff,” is a desirable property in a global marketplace where regulators cannot guarantee that patients will not be switched back and forth from the reference and test products on a daily, weekly, or monthly basis when their prescription is filled at the pharmacist, and formulations are switched to the least-expensive product available in stock. International regulators cannot at present ensure that all patients will be switched to the new formulation consistently, immediately, and permanently. Use of metrics such as that proposed by the FDA may place patient populations at increased risk of side effects or ineffective switching because of marketplace forces beyond regulatory control.

Another benefit of the KLD metric is that it does not necessarily require the use of a three- or four-period replicate design to assess individual bioequivalence. The KLD metric, as a measure of individual bioequivalence, seems to identify more data sets as being of concern than the proposed FDA metric. This appears to be because of the ability of the FDA metric to reward novel formulations for which the within-subject variance is decreased relative to the reference product and the use of the mixed scaling procedure. While the KLD metric may be viewed as being a more “stringent” criterion than the FDA metric, it appears to identify those data sets where changes in formulation are of potential concern.

In conclusion, the results of simulations and retrospective analyses to date indicate that the KLD metric is a potential alternative to the FDA-proposed metric, offering some technical and interpretive advantages and preparing the ground for a reasonable and mathematically tractable methodology for bioequivalence evaluation.

Laboratory Analyses

Michael J. Klepper

Integrated Safety Systems, Inc., Cary, North Carolina, U.S.A.

Abstract

In clinical trials, laboratory analyses may be used to determine the efficacy of a biopharmaceutical product. This entry describes the most commonly used methods of laboratory analysis as well as some of the scientific issues associated with this type of analysis.

INTRODUCTION

In clinical trials, laboratory analyses may be used to determine the efficacy of a biopharmaceutical product such as in trials evaluating the effectiveness of lipid-lowering drugs where changes in cholesterol levels would be a primary efficacy endpoint of the study. However, analyses of laboratory changes are more often used in the evaluation of biopharmaceutical product safety. Changes in laboratory values observed during clinical trials may signal organ dysfunction/toxicity, hypersensitivity reactions, or important physiological and metabolic changes. Such changes may be due to the investigational drug under study, be a result of an underlying disease process unrelated to the investigational drug, be due to a concomitant medication taken by a patient participating in a clinical trial, may represent a drug interaction, or may be spurious. Moreover, large laboratory changes seen in an individual or a small group of patients may have greater clinical significance than small changes affecting a larger number of patients taking the investigational product. A variety of analyses is used in evaluating laboratory changes, and the results from each analysis give different insights into such changes. In dealing with changes in laboratory values, some analyses may reveal statistically significant changes that are not clinically significant, and conversely clinically relevant changes may not achieve statistical significance. Observed changes in laboratory values during a clinical trial may signal that such changes may be due to a biopharmaceutical product under investigation; however, clinical correlation is important to determine whether this signal is valid and if so whether the change is clinically important.

METHODS

Laboratory Analytes Measured

In clinical trials, laboratory parameters that are collected and analyzed fall into three main categories: hematology, chemistry, and urine.

[Table 1](#) summarizes by category the laboratory parameters that are routinely measured in clinical trials. Depending on the biopharmaceutical product being studied, and the known or theoretical properties and side effects of the product, other laboratory parameters may also be collected. For example, 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitors, also known as statins, are effective agents in lowering cholesterol, low-density lipoprotein (LDL), and very low density lipoprotein (VDRL). These drugs may also damage skeletal muscle, which is often reflected by an increase in creatinine phosphokinase (CPK), a muscle enzyme.^[1] For these reasons, cholesterol, LDL, VDRL, and CPK levels would routinely be measured in clinical trials dealing with statins.

Changes in hematological parameters usually reflect effects on the bone marrow, excessive blood loss such as anemia from bleeding, or increased rate of destruction based on hypersensitivity reactions. Chemistry parameters reflect a variety of different organ functions and other physiological changes including liver and kidney function as well as metabolic changes. Changes in the urine may be specific to the urinary system, e.g., the presence of WBC casts seen in renal disease, or be reflective of a disease process unrelated to the kidney, e.g., the presence of glucose and ketones in the urine in a patient with uncontrolled diabetes. Often a disease will manifest itself with changes seen in more than one laboratory category; for example, a patient with renal failure may be anemic, have elevations of BUN, creatinine, and serum potassium, and have an abnormal urine analysis. Laboratory parameters can be organ-specific or nonspecific; for example, ALT is an enzyme with greatest specificity for the liver, whereas AST is an enzyme that is found in skeletal and cardiac muscle and the liver. Standard laboratory and medical texts should be referred to for more detailed discussions regarding the clinical implications and significance of laboratory test changes.

Table 1 List of Laboratory Analytes by Category

Hematology	Hemoglobin (HBG)
	Hematocrit (HCT)
	Red blood cell (RBC) count
	White blood cell (WBC) count
	Differential WBC count
	Neutrophils
	Lymphocytes
	Eosinophils
	Basophils
	Monocytes
	Platelet count
Chemistry	Alanine aminotransferase (ALT, SGPT)
	Aspartate aminotransferase (AST, SGOT)
	Alkaline phosphatase (ALP)
	Glutamyl transferase (GGT)
	Lactate dehydrogenase (LDH)
	Total bilirubin
	Blood urea nitrogen (BUN)
	Creatinine
	Albumin
	Total protein
	Sodium
	Potassium
	Chloride
	Calcium
	Phosphorus
	Uric acid
Urine	Glucose
	Cholesterol
	Triglycerides
	pH
	Specific gravity
	Presence of glucose, ketones, RBCs, WBCs, bacteria, casts, and crystals

Grouping of Laboratory Analytes

Because a number of different laboratory analytes may reflect similar organ or physiological dysfunction, certain related laboratory analytes when grouped together may aid in the review of laboratory changes. For example, both hemoglobin and hematocrit are related to red blood cells and should be displayed next to each other. Liver abnormalities might show changes in ALT, AST, bilirubin, GGT, LDH, and ALP and therefore these analytes should be displayed together. Renal function often affects both BUN and creatinine and, therefore, these values should also be grouped

together. Although arbitrary, the analytes listed in [Table 1](#) have been grouped in ways that facilitate medical review.

Reference Range of Laboratory Analytes

Each laboratory establishes its reference range for each analyte by obtaining laboratory measurements of subjects believed to be healthy and “normal.” It is assumed that the laboratory values of the healthy and normal population follow a Gaussian distribution and the mean and standard deviation (SD) of each analyte are calculated. Consequently, 95% of the healthy and “normal” population is expected to have values that fall within ± 2 SD of the mean.^[2] For some analytes, other factors such as age and gender affect the reference range. For example, females have a lower reference range for red blood cells, hemoglobin, and hematocrit due to blood loss during menstruation and gender differences in lean body mass. Age affects the reference ranges for the enzyme alkaline phosphatase. This enzyme can be found in a number of tissues especially bone and liver. Because of bone growth reflected by an increase in alkaline phosphatase values, the reference range for this analyte in children is predictably higher than the reference range in adults.

Units of Laboratory Analytes

The International System of Units (Système International Units, SI), which is based on the metric system^[3] is likely to become the global standard. Until this happens, laboratory values collected in clinical trials may report values in conventional (units still used in some United States laboratories) or SI units. In order to pool data across sites and countries such data need to be converted to the laboratory units selected for analysis (see the “Scientific Issues” section).

Types of Laboratory Analyses

In clinical trials, any change from baseline may represent an effect due to the biopharmaceutical product under investigation. The laboratory analyses that are utilized compare the value(s) obtained during the treatment period to those obtained at baseline, with baseline values usually defined as the last measurement before a subject received treatment of the investigational product, placebo, or comparator agent. The International Conference on Harmonization (ICH) and the Food and Drug Administration (FDA) have issued guidances regarding laboratory analyses for clinical studies^[4] and integrated summaries of safety for product registration.^[5–7] The types of analyses utilized for laboratory data obtained from clinical trials generally fall into four main types. The first type includes descriptive statistics such as mean changes, mean percentage changes, and median changes and analyses, which measure central tendency. Another type of analysis examines the number

of patients who have shifts in laboratory values from one category at baseline to a different category postbaseline, i.e., shift tables. Of particular clinical importance are the analyses that evaluate the number of patients with clinically significant laboratory changes, i.e., outliers. The fourth type of analysis examines the incidence of laboratory-related adverse events.

Means, Mean Percentage Change, and Medians

Mean change comparing postbaseline values to baseline values is one of the established methodologies employed in the analysis of laboratory data. Because such changes may be very small, mean percentage change from baseline may be used instead. Standard deviations are also calculated to determine the variability of the data. Means are used for data that are normally distributed otherwise the median is used.^[8] For comparative clinical trials, the difference in change from baseline between treatment groups is compared and a determination is made as to whether or not the difference is statistically significant, i.e., *p* values of ≤ 0.05 . For studies with no comparative group, changes from baseline are described.

Shift Tables

Two types of shift tables can be utilized in assessing categorical changes. The first type of shift table evaluates the number (%) of subjects with a laboratory value below (L) normal or normal (N) at baseline that shifts to a value above normal (H) postbaseline. The number (%) of subjects with above (H) normal or normal (N) values at baseline who had postbaseline values below (L) normal is also calculated. Postbaseline values that remain within the same baseline category, indicating no change, and abnormal baseline values that become normal during the treatment period are usually not included in the shift table analysis in order to highlight the more clinically important changes. An example of this type of shift table is shown in Table 2.

Categorical analyses can also be used to examine the number of subjects in each treatment group with baseline values that reached a certain prespecified change, e.g., the number (%) of subjects with creatinine values that increased 25% from baseline.

Table 2 Example of a Shift Table—Investigational Product

Baseline	On-treatment (<i>N</i> = 100)		
	Low	Normal	High
Low	X	X	4 (4%)
Normal	2 (2%)	X	10 (10%)
High	5 (5%)	X	X

X = shifts that are not clinically meaningful.

Analysis of Outliers

It is also important from a clinical perspective to look at laboratory values that are not only abnormal but fall into the category of clinically significantly abnormal values, i.e., outlier values. Such values may indicate a serious clinical condition that requires further evaluation and treatment. One way of looking at such outliers is by constructing scatterplots. Posttreatment values that indicate no change from baseline values would fall on a 45° line. Values that fall way above or below this line would indicate outlier values. Once identified, such values would have to be explored further. Another method is to use the categorical analysis discussed above to analyze the number (%) of subjects who develop clinically significant values postbaseline. For example, a clinically significant abnormal value for platelets is defined as $\leq 75 \times 10^3/\text{mm}^3$,^[6] the reference range varies depending on what laboratory is used but is generally in the range of $(150 \text{ to } 350) \times 10^3/\text{mm}^3$. The risk of developing spontaneous bleeding episodes that may become life-threatening increases as the platelet count decreases. From a clinical standpoint, it is important to determine how many subjects develop clinically significant decreases in platelet counts. This type of analysis summarizes the number (%) of subjects with one or more clinically significant values for a given analyte. Because change from baseline like the other laboratory analyses discussed above should be the primary focus of the analysis, it is recommended that only those subjects who had normal values at baseline and had one or more clinically significant values during the treatment period be included in the analysis. The Neuropharmacology Division of the FDA has established clinically significant threshold values for some laboratory analytes^[6] that can be used for this type of analysis. Subjects who had an abnormal baseline value could also be included in such an analysis if a clinically significant change for the baseline abnormal value is defined for that analyte, e.g., any value that was 50% greater than the abnormal baseline value. Establishing clinically significant thresholds for those laboratory values abnormal at baseline is usually left to medical judgment and the thresholds chosen should be clearly documented. In the categorical analysis of clinically significant changes, a subject with more than one clinically significant (CS) value for a given analyte is counted only once, but all values for this subject should be shown in a laboratory listing as described below. For trials that include placebo or a comparator control group, the number (%) of subjects in the investigational product group would be compared to the number (%) of subjects who received placebo or a comparator agent. Because the number (%) of such subjects in any given treatment group is expected to be low unless the product under investigation is toxic, testing for statistical significance is usually not appropriate and could be misleading because a low incidence is unlikely to show statistically significant differences. A small difference between

treatment groups, however, may still be clinically important. Table 3 is an example of clinically significant changes in two related analytes AST and ALT. These results would indicate that there may be both a drug and dose effect of the investigational product compared to placebo. Because the changes are seen for both AST and ALT, these findings may be indicative of a liver-related problem.
